£80,000. But this sum represented less per head of patients treated than in previous years. Three explanations for this reduction were given by Lord Hambleden. First, a deficit in the working of the association in 1925 had to be paid off; secondly, there had been an excessive increase in the demand for hospital treatment during part of the year under review; thirdly, heavy expenses had been incurred for extra hospital benefits, and to found necessary to curtail these extra hospital benefits to a maximum of 15 per cent. of the contributors, and to suspend altogether dental benefit for dependants, and to Lord Hambleden's speech it was evident that one of the problems encountered by the association was the tendency of people to join when there was a prospect of themselves or their dependants requiring hospital treatment. The Hospital Saving Association possesses an organ called the *Contributor*, with a circulation of 60,000 copies. Lord Dawson, in his address to the meeting, described the progress in knowledge which was obtained through hospitals. Mr. McAdam Eccles was re-appointed a member of the executive council. From the size of the organization it is evident that the ideas of the late Dr. Gordon Dill have taken root and are fructifying.

#### JUBILEE OF UNIVERSITY COLLEGE, BRISTOL.

In celebration of the fiftieth anniversary of the foundation of the University College, Bristol, a reception was held on December 3rd at the University, and afterwards a meeting in the Great Hall, when the chair was taken by the Vice-Chancellor, who said that the men and women of fifty years ago sowed the seed of which to-day the harvest was being reaped. There was no better reply to those who were apt to scoff at the Victorian age than to ask them to contemplate the magnificent optimism of the men and women who in the great cities of the country laboured to found university colleges out of which so many flourishing universities had grown, or to read the list of distinguished men who with real missionary zeal taught in these university colleges. Balliol College and New College, Oxford, took a very generous part in financing University College, and both were represented.

#### The Function of a University.

The Master of Balliol (Dr. A. D. Lindsay) recalled what Professor Jowett had said about University College, Bristol. The chief point he stressed in his speech was the need he felt for the universities to extend their borders, adding that it was intolerable that university education should be confined to a small minority. Another point in the speech was the need for combining a liberal education with a scientific education, and he welcomed the fact that the medical school at Bristol was among the foremost in insisting that the arts side should be taken in with the scientific side. The other point he stressed was that college was a place where men lived together and learnt together, and that if they forgot that they forgot a great deal of what went to make up a university. It was extremely important that our universities should be the centre of our national life, and he was proud of the part University College had played in founding this centre of inspiration for Bristol. Professor Lloyd Morgan said old students had told him how much they owed to men like Professors Silvanus Thompson, Rowley, and Fanshawe. The difficulty in the early days was to keep the arts side alive. This, however, was done under distinguished men like these. Mr. F. Richardson Cross, Dr. T. D. Sibley (principal officer of the University of London), and Dr. H. S. Hele Shaw also spoke.

#### PRE-IMMUNIZATION AGAINST TUBERCULOSIS.

In November a report was presented to the Port Sanitary and Hospitals Committee of the city of Liverpool by Dr. J. G. Moyles, who is chairman of the committee, and Dr. C. Rundle, medical superintendent of the Fazakerley Hospitals, describing a visit they had paid to Dr. Calmette at the Institut Pasteur in Paris. The report describes the theories upon which Dr. Calmette bases his use of B.C.G. for the pre-immunization of infants against tuberculosis. The views and methods of Dr. Calmette were stated in detail in the *BRITISH MEDICAL JOURNAL*, March 27th, 1926, p. 581. Drs. Moyles and Rundle found that the results claimed for the inoculation in infants were very striking; but at the same

time the disparity between the figures for alleged infantile mortality from tuberculosis in many Continental cities and the mortality from the same cause in Liverpool was such that the observers could only suppose that there must be a divergence in standards of diagnosis. Drs. Moyles and Rundle obtained, by the courtesy of Professor Calmette, a small quantity of B.C.G. This is now being examined by Professor J. M. Beattie, the city pathologist, and a similar investigation is said to have been undertaken by the Ministry of Health. As is usual when reports such as that of Drs. Moyles and Rundle are made, the lay press produced articles headed "Stamping out of consumption." Whether the public benefit or not by these premature announcements need not be a matter of much concern to the investigator. But it is important that the claim of a scientist such as Professor Calmette should be properly examined, whatever the effect may be on present notions about tuberculosis and its treatment.

#### BRISTOL MEDICAL DINNER.

The annual dinner of the Bristol Medical School was held on December 2nd on the premises of the University Union at the Victoria Rooms. About 150 past and present students and members of the staff attended. Professor Fawcett, F.R.S., dean of the Faculty of Medicine and Professor of anatomy, presided, and Dr. J. T. Wilson, F.R.S., president of anatomy in the University of Cambridge, was the guest of the evening. In proposing the toast of "The Bristol Medical School," he congratulated it on its close association with the University. In the profession of medicine it was not mere craftsmen, but men of broad outlook and culture, who were wanted, and it was this which distinguished a graduate of a university from a student of a technical college. He referred to his thirty years' experience at the head of the medical school in Sydney, where he had watched the numbers of students increased gradually from a mere dozen until they exceeded a thousand. Dr. R. S. Statham and Mr. J. Newton replied for the medical school. Mr. A. J. M. Wright proposed the health of the President. After the dinner a most successful reception and dance was given in the same building by the wives of the staff.

#### STREET ACCIDENTS IN LONDON.

The London County Council is calling for a full inquiry as to the measures which can be taken to lessen the great loss of life and limb due to street accidents in London, and is asking the London and Home Counties Traffic Advisory Committee, which is the authority for advising on measures for facilitating and improving the regulation of traffic, to summon a conference of all concerned. The number of deaths in street accidents in the metropolitan police area during the first nine months of 1926 was 710, as compared with 840 for the whole year 1925. The number of persons killed yearly has increased nearly fivefold in twenty-five years, and the number of injured (40,173 last year in Greater London) has increased in much the same proportion. Nearly three-fourths of those killed are pedestrians, and between one-third and one-fourth of them are children. With regard to comparisons with other cities, the London streets seem to be more deadly than those of Paris, but less so than those of New York, where, with a population equal to three-fourths of that of Greater London, it is admitted that the attitude of a number of the victims adds to the difficulties of the problem. Subways are provided, but people will not take the few steps necessary to make use of them, and prefer to take risks in getting among the traffic. It is considered that regulations should not be made on the assumption that pedestrians will frequently not exercise the necessary care, and that the use of streets by vehicles must be governed accordingly. The need for retention of speed limits in urban areas should be thoroughly investigated. The provision of more street refuges appears to be essential. Experiments with definite street crossings, with and without police, should have useful results, and above all a closer and more effective control by the police is called for to diminish, not only cases of dangerous and negligent driving, but the inconsiderate use of the streets by drivers of motor vehicles.

## REGISTRATION OF NURSING HOMES.

The report of the Select Committee on the inspection and supervision of nursing homes has been approved generally by the London County Council, but it takes exception to the recommendation that appeals against refusal or cancellation of registration may be made to a referee appointed by the Ministry of Health. It believes that the procedure laid down in regard to lying-in homes in London is preferable—namely, that such appeals should be made to a magistrate's court. Another recommendation, that the supervising authorities may delegate their powers to a committee upon which both doctors and nurses shall have some representation, is also regarded as open to objection, and it is considered that the County Council should have complete freedom of action either to delegate this power to one of its existing committees or to a specially constituted committee which may include a specified proportion of persons of experience appointed by the Council.

## EWELL COLONY.

Ewell Colony, after its evacuation by the Ministry of Pensions, is to be used by the London County Council during the next two years for the accommodation of 100 men and 329 women patients certified under the Lunacy Acts. Dr. Leonard Henry Wootton, M.C., deputy medical superintendent of Colney Hatch, who has been acting at Ewell while it has served as a hospital for pension cases, has been appointed medical superintendent as from February 1st next at a salary (based on pre-war rates, and subject at the moment to an addition of £195) of £800 a year, together with an unfurnished house.

## Scotland.

## SCOTTISH ASYLUM REPORTS.

THE 106th annual report of the Dundee Royal Lunatic Asylum shows that during the year ending June 21st, 1926, 83 patients had been treated. Among these there had been 7 deaths, all due to natural causes; 2 were of epileptics who had suffered from that disease for many years; 6 of the 15 persons admitted were voluntary patients, which shows that increasing advantage is being taken of early admission before the derangement has become so marked that compulsory certification is necessary. The directors' report shows that the sum received for the board of patients in Gowrie House was £5,148, and that during the year seven patients had been admitted at reduced rates of board, varying from £50 upwards.

The report of the Royal Asylum of Montrose for the year ending May 15th, 1926, shows that the number of patients on the register at the end of the year was 726, and that the total number of cases treated during the year was 854. The average age on admission was 45.1 years, while one patient was under 15, seven under 20, and thirteen over 70 years of age. In 39 of the admissions there had been a previous attack of mental disorder. As a general rule the health of those admitted was much below par, and 36 were very weak. The general experience had been that as physical health improved under treatment there was usually a corresponding mental change. The effect of the present depression in trade had been shown by an increase of cases due apparently to unemployment; they numbered 13, as compared with 6 in the preceding year. The increase in attacks apparently due to alcohol—18 as compared with 7 in the preceding year—might, it was thought, partly result from the same cause. Attention is drawn to the fact that too little recognition is given by the public to the tendency in cases of mental depression to develop suicidal tendencies. Out of 39 cases of melancholia, 24 were acutely suicidal on admission, and 12 had made attempts on their lives before being certified. At the beginning of the year there were 23 voluntary boarders, and 16, or 32 per cent., of the total private admissions came under treatment in this way.

The sixty-second annual report of the Inverness District Asylum, covering the year to May 15th, 1926, shows that there were then on the register 717 persons, and that 867

patients had been under treatment during the course of the year. The admissions during the year numbered 162, and were 39 more than in the preceding year. They included 72 cases of melancholia, 47 cases of mania, 33 cases of dementia, of which 12 were secondary to other mental disorder, and 19 associated with senile decay; there were also 7 cases of congenital mental deficiency. Hereditary or family predisposition was found to exist in 69 of the 162 cases, and in 58 of the cases there had been at least one previous attack of mental disorder. Senility was the assigned cause in 39 cases. The marked increase of admissions during the present year is explained as being related to the admission of private patients to public mental hospitals and the reception in these hospitals of voluntary patients assisted by the rates.

## ROYAL INFIRMARY OF EDINBURGH.

At a meeting of the board of managers of Edinburgh Royal Infirmary, held on November 22nd, it was reported that the managers had received the property of Beechmount, Murrayfield, valued at £15,000, bequeathed by the late Lady Mary Anne Anderson; it is to be converted into a convalescent home; the same donor had also left a sum of £5,073 to the institution. It was reported also that the number of cases awaiting admission to the infirmary at November 1st, 1926, was 1,856. Attention was drawn to the fact that the waiting list had for a long time stood at over 2,000, and it was explained that the fall in numbers was the result of the opening of new wards in the ear, nose, and throat department. The number of cases now awaiting admission to that department was 97, as compared with 237 in the previous month.

## CHILD WELFARE IN GLASGOW.

A pamphlet explaining a scheme for maternity and child welfare in Glasgow has been prepared by Dr. A. S. M. Macgregor, M.O.H. for the city, on the instruction of the health committee. The basis of the child welfare scheme is to be the consultation centre, working in combination with a system of regular home visitation of trained and voluntary visitors. The child welfare staff in Glasgow includes eight medical officers (women) and thirty-nine nurses. The expenditure involved in connexion with the maternity and child welfare work carried out during the year to May 31st, 1926, was £122,215, of which approximately £50,000 was received from Government grants. The charge of £72,000 against the rates was equal to 1.663d. in the £. For the current year the net charge is estimated at £63,450, equal to a rate of 1.417d. in the £.

## BENEFACTIONS TO GLASGOW MEDICAL CHARITIES.

The late Mr. Robert Allison of Paisley, who died recently, has left a large number of legacies to various medical charities and other benevolent institutions in the West of Scotland. The total sum is £25,500; the residue of his estate, which is expected to be considerable, is to be divided between Paisley Infirmary, Glasgow Royal Infirmary, Glasgow Western Infirmary, and Glasgow Victoria Infirmary. Among the other medical charities that will benefit to the extent of £1,000 each are the Paisley Eye Infirmary, Glasgow Eye Infirmary, the Glasgow Samaritan Hospital for Women, Glasgow Cancer Hospital, and Glasgow Royal Hospital for Sick Children; the Glasgow Hospital and Dispensary for Diseases of the Ear, and Glasgow Hospital for Skin Diseases, will each receive £500.

## EDINBURGH CONVALESCENT HOME.

The Astley-Ainslie Institution for convalescent patients from the Royal Infirmary of Edinburgh is now proceeding with the second portion of its scheme. The first portion was sanctioned about a year ago and two pavilions for male and female patients, each accommodating about forty persons, are now nearing completion. The second portion of the scheme provides for the erection of three new blocks, including a nurses' home, sitting-rooms, lecture room, and other administrative buildings. The whole is planned for 150 convalescent patients, and is designed to act as an auxiliary hospital between a convalescent home and a hospital in which treatment is

provided. The scheme is to a great extent on the lines of the chief recommendation made by the Departmental Committee of the Scottish Board of Health for the establishment of subsidiary hospitals, connected with general hospitals to relieve the congestion in the latter.

## Ireland.

### MEDICAL RESEARCH IN IRELAND.

A discussion on medical research was held on November 19th by the Section of Pathology of the Royal Academy of Medicine in Ireland. Dr. J. W. Bigger, professor of pathology and preventive medicine in Dublin University, who was in the chair, gave an opening address, in which he limited himself to laboratory research, describing its motives, prospects, methods, and embarrassments. The difficulties of the research worker were partly inherent in his work and partly forced on him by the necessity of engaging in teaching, routine diagnostic work, or public health; it ought not to be necessary to hold over research work until such daily duties had been finished. The present position in many university laboratories of pathology and bacteriology was a serious bar to progress in research. He pleaded for the adequate payment of research workers and for the encouragement of medical research in Ireland, where hitherto it had been much neglected. Dr. T. G. Moorhead dealt with clinical research, of which, he said, there was as much need to-day as there had ever been. The tendency to replace the teaching of therapeutics by education in scientific pharmacology was, he thought, a mistake, since the action of drugs on healthy animals might differ from their effect on sick patients. To ensure collaboration between clinicians and laboratory workers due credit should be given to the clinical aspect of the laboratory worker. Dr. Moorhead deplored the meagre salaries of university teachers generally, and hoped that a new spirit of progress in the Irish Free State would result in a considerable increase in the endowment of medical research. Mr. W. Doolin referred to the fame of Dublin as a centre of medical investigation in the time of Abraham Colles, Cusack, and Henry Marsh. In the present state of poverty of the country Ireland was unable to keep up with wealthy countries, such as America, in the race of scientific progress, and it was impossible to carry on research at present on a grand scale. Clinical research needed greater consideration than it was receiving, and very correctly performed surgical operation was a physiology of the surgical worker. A whole-time teaching and research surgical unit should be established for the study of such problems as the true significance of Graves's disease, the prevention of intraperitoneal adhesions, and the physiology of bone. The present inadequate training of students in research was lamented by Dr. T. T. O'Farrell, who considered it the cause of lack of interest after graduation, which accounted for the paucity of research workers. Professor J. M. O'Connor agreed that all research work should be associated with teaching so far as possible. Elaborate equipment was relatively unimportant, and much valuable research could be done with inexpensive apparatus. Dr. W. MacFetridge thought it was impossible to expect funds from the Government; the only chance of obtaining money lay in private generosity. He believed that by providing in Ireland a body corresponding to the Medical Research Council some support would be obtained. Whole-time research workers were needed in Dublin and England the Medical Research Council had first been financed by money derived from the National Health Insurance scheme, and thought that something similar should be adequately paid. More young men should be admitted to hospital staffs; in some cases small salaries were already being paid to enable them to carry on work in hospitals after graduation. In Dublin men were needed to direct research as much as to perform the actual investigations.

## Correspondence.

### LEPROSY: ITS TRANSMISSION AND TREATMENT.

SIR,—Of recent years a number of statements have appeared, both in the medical and the lay press, on the curability of leprosy by various forms of treatment. Certain of these statements have been made by men with long and close experience of the disease, who have had ample opportunity of testing the value of the particular treatment they advocate, in a large number of cases and over a long period of years. Equally forcible statements have been made by others, based on isolated cases, without having them under observation for a sufficient time to know if any improvement which may have occurred was permanent.

In the present state of our knowledge statements with regard to the cure of leprosy, in the ordinary sense of the term, as understood by the lay mind, are to be deprecated, as they are not only misleading to the public, but are apt to cause bitter disappointment to the patients themselves.

Everyone with considerable experience of the treatment of leprosy has had cases in which the disease has undergone periods of more or less complete remission while under some form of treatment. These remissions have been too often temporary, and, after a longer or shorter interval, especially in early cases, a recrudescence has almost invariably occurred. It is necessary, therefore, before making definite statements with regard to cure, that the treatment employed should be thoroughly tested, and that the cases in which it is being used should be observed over a period of years.

Another instance of a claimed cure appeared in the last issue of the *BRITISH MEDICAL JOURNAL*, in a paper by Dr. E. Graham Little, under the heading of "Acute nodular leprosy originating in this country and cured by vaccine treatment." As this case has only been under the writer's observation for about six months, it seems to us that it is premature to regard it as cured, however much the appearance of the patient has improved during the treatment.

There is another point in the title of the paper which is misleading and somewhat alarming—namely, the description of the case as having originated in this country. The case was that of a Chinese student, who was shown at the Royal Society of Medicine in May, 1926, and who had only arrived in this country in November, 1925. He was seen by one of us on May 28th, when, in addition to the nodular outbreak, he showed ample signs of having had only leprosy for an indefinite period, certainly longer than six months. Both his ulnar nerves were thickened, there was anaesthesia in the area of distribution of the ulnar nerve on the left hand, and commencing "main en griffe." Three contact cases of leprosy, to our knowledge, have originated in this country of late years in patients who have never been out of the country, and who have been infected by long and close contact with relatives who brought the disease from abroad. These were reported by one of us in the *BRITISH MEDICAL JOURNAL* (1925, vol. i, p. 107). The case referred to above does not belong to that category.—We are, etc.,

GEORGE C. LOW.  
J. M. H. MACLEOD.  
PHILIP MANSON-BARR.  
JAMES H. SEQUEIRA.

December 3rd.

### ADVISORY COMMITTEE ON SPIRITUAL HEALING.

SIR,—We, the undersigned medical members of the Archbishop of Canterbury's Advisory Committee on Spiritual Healing, should be grateful to any medical practitioner who could supply us with information regarding patients who have received benefit from spiritual healing, whether through an organized mission of healing or individually. We appreciate that names could not be given without the permission of the patients concerned, and although we should like to have them where consent is given, we should, nevertheless, be glad to receive any information that can properly be supplied, as the desire of the committee is to

collect evidence as to the value of spiritual healing, and the type of person most likely to be helped by it.

Letters may be addressed to any of the signatories.  
—We are, etc.,

WILLIAM BROWN.  
H. CHARLES CAMERON.  
J. WALTER CARR.  
W. McADAM ECCLES.  
PERCIVAL H. S. HARTLEY.  
MAURICE CRAIG,

Honorary Secretary.

London, N.W.1, Dec. 6th.

### THE PUBLIC, THE DOCTOR, AND THE MASSEUSE.

SIR,—Those branches of treatment that are described collectively as "physical" are rapidly increasing in scope and importance, and consequently a situation has arisen that needs very careful review.

The number of qualified medical men who have studied these methods seriously is very small. The number of patients who seek it is very large. Consequently the vast majority of these must place themselves in the hands of masseuses who lack the competent supervision that they need.

To avoid unnecessary detail I will dismiss the subjects of massage, and that part of medical electricity that comes under the general heading "galvanism" and "faradism," with the remark that they are, as a rule, free from danger, and their practice by those of mediocre understanding leads more to results that fall far short of those attainable by a fully qualified doctor who is an adept at this particular branch of medical study.

When we come to the subject of diathermy and artificial phototherapy, however, the case is much more serious.

The diathermy current is being used more and more as time goes on, and it is found to be of great value in stimulating the physiological action of certain tissues, and as a destructive agent in various "surgical" operations.

Fortunately the nature of the application in these "surgical" methods places them out of reach of the unqualified operator, but the "physiological" application of this current—that is to say, the passage of moderate diathermy current through portions of the body in the treatment of rheumatoid and other affections—is constantly carried out by masseuses, and entails much danger to the patients.

The effect of the current is to raise the temperature of the deep tissues through which it passes. If the current is applied through the skin by means of large electrodes the heating effect on the skin may be slight, but deep tissues traversed by the current may be heated up to the point of destruction without any sensation of pain or discomfort being felt by the patient.

Not very long ago I saw a patient who had been treated by a masseuse for brachial plexus neuritis. Pads had been applied to the outer aspect of each shoulder, and the diathermy current passed through the shoulder-joints and intermediate cervical region between the two pads. The arms had been placed in such a position that the current had been concentrated through the shoulder-joints. No pain was felt, but after several treatments one of the shoulder-joints was rigidly ankylosed by the destruction and sealing up of the synovial membrane and capsule, the condition being absolutely incurable. The movement of the opposite shoulder was permanently limited.

When the current is passed through the sacral region in a careless manner between electrodes placed on the sacrum and the vesical region of the abdomen in front, or else from hip to hip, there is a great danger of concentration of the current through knuckles of gas-filled intestine. The result of this may easily be ulceration and adhesions coming on at a later date and quite unsuspected by the doctor whom the patient may consult for the serious symptoms that ensue. Again, the simple passage of more than a safe amperage through, say, the ankle-joint, may seal up lymphatic vessels, with permanent and serious results.

The board of examiners of the Chartered Society of Massage and Medical Gymnastics, after special consultation, decided to exclude diathermy from the curriculum and

examination of the massage students, yet large numbers of them practise it daily.

The pity is all the greater because in the safe and competent hands of a doctor who has specialized in this form of treatment, diathermy is magnificently successful in many cases of chronic inflammation.

Phototherapy is another form of treatment that offers much danger to the patient in incompetent hands. The constitutional effect of treating the skin by ultra-violet rays is obtained by the radiation of cholesterol in the cutaneous cells. A factor is produced which profoundly influences the general nutrition of the body. Many patients are very sensitive to this factor. The danger of overdose arises particularly when the skin has ceased to be inflamed by any ordinary intensity or duration of the radiation. The constant production and absorption of the factor above referred to in excessive doses may then produce marked symptoms of malaise and exhaustion in even a healthy person. In those who are already ill the result is often very harmful. Patients who are losing weight under a certain dosage may put on weight when the dosage is reduced.

The symptoms produced by phototherapy being (except the easily detected dermatitis) constitutional, the treatment should therefore only be given by doctors, or properly qualified hospital nurses, who are trained to observe them. To place it in the hands of others is a great mistake. Even the trained nurse should have the actual supervision of a doctor who has really studied the treatment, and the growing tendency of nurses to set up in "private practice" with clinics of their own is much to be deprecated. In the case of the masseuse the danger is infinitely worse.

Consideration of what has been said here must surely lead to much uneasiness as to the direction in which physical treatment is drifting.—I am, etc.,

London, W.1, Nov. 28th.

G. MURRAY LEVICK.

### ERYTHEMA NODOSUM IN MEMBERS OF A FAMILY.

SIR,—In his interesting communication on this subject (BRITISH MEDICAL JOURNAL, December 4th, p. 1049) Mr. D. Gordon Robinson states that on searching the literature he can find no record of such a seemingly "infectious" nature of erythema nodosum. In the *British Journal of Children's Diseases*, London, 1925, xxii, p. 133, after referring to the association of erythema nodosum with various infectious microbic septicaemias besides "tuberculous bacillaemia," I wrote:

"In many cases, however, the cause or causes of erythema nodosum remain altogether obscure, so that there is some justification for the term 'nodal fever' (*febris nodosa*), introduced by Dr. A. A. Lendon in 1905. . . . Such a view would account for the occasional small epidemic outbreaks, such as have been described by E. Ledoux (*Revue de Médecine*, Paris, 1923, xl, p. 321). A familial constitution ('familial soil'), in addition to familial exposure to infection, might help to account for familial occurrence, as that noted by P. Wöringer in his paper on familial erythema nodosum (*Journ. de méd. de Paris*, 1923, xlii, p. 241)."

—I am, etc.,

London, W.1, Dec. 5th.

F. PARKES WEBER.

### TREATMENT OF ACUTE POLIOMYELITIS.

SIR,—There are certain statements in Sir Robert Jones's letter in your issue of November 27th (p. 1018) which, coming as they do from such an acknowledged authority, will become axiomatic in the treatment of acute poliomyelitis unless they are shown to rest on an incomplete appreciation of the recent developments and possibilities of electro-physics in relation to physiology.

The first of these is the statement that "it is certain that the child is in considerable danger from premature massage and electricity." A patient suffering from acute poliomyelitis is in no danger from either the one or the other, provided always that a fully medically qualified physio- or electro-therapist be consulted, as he is, or should be, equally aware with the orthopaedic surgeon of the need for complete rest and the importance of refraining from any procedure involving exposure, movement, or stimulation.

The second statement to which I desire to draw attention is, "In the presence of acute symptoms it is dangerous to stimulate the peripheral ends of nerves connected with haemorrhagic and inflamed centres." This statement by itself is unexceptionable; in its context, however, it obviously means that all "electricity" must necessarily be stimulating and cannot be sedative, and therefore is dangerous. If this reading of his meaning is accurate, then Sir Robert's data are incorrect, as all "electricity" is not, *ipso facto*, stimulating, as electro-therapeutical currents exist which are entirely sedative.

If the injured cord lay more superficially and Sir Robert Jones could, with a minimum amount of movement, foment it where the "haemorrhagic and inflamed centres" exist, would he not unhesitatingly do so? I feel convinced he would. Has he ever propounded this problem to a competent electro-therapist and made trial of the resulting suggestion? If he has not and will do so, I can assure him, from personal experience, that he will be pleasantly surprised with the results. —I am, etc.,

London, W.I., Nov. 20th.

C. B. HEALD.

Sir,—The necessity for and the great value of rest in the treatment of acute poliomyelitis was stressed by you, in your leading article of November 20th (p. 947), and also by Sir Robert Jones in your correspondence columns of November 27th.

While recognizing the essential importance of rest as a curative factor in the treatment of the paralysis left by this disease, it seems to me that there does come a time when this Fabian policy—as Sir Robert Jones calls it—should give place to, or rather should be combined with, a more active form of treatment. Rest as the only form of treatment must, if logically pursued, finally result in immobilization.

Sooner or later every practitioner in charge of a case of poliomyelitis has to face the question of the possibility of his patient's return to an active life. Whether rest has been followed out for twelve months or for two years—and personally I favour at least twelve months' recumbency in lower limb paralysis—it must ultimately come to an end.

The final judgement of parents on our management of a case of poliomyelitis is based on the subsequent proportional ability of the individual to lead a normal life and to earn a living. Put shortly it is this—can our patient ultimately walk (if a lower limb paralysis), and can he use his hands and arms to obtain a livelihood (if an upper limb paralysis)?

A long view of this character must be taken from the beginning of treatment if full ultimate success is going to be obtained. When careful attention has been paid to the details of rest, as so frequently and so ably laid down by Sir Robert Jones, this particular part of the treatment is comparatively easy.

The real difficulties of treatment are experienced when the attempt is made to regain movement. Much has been written and many investigations made regarding the prevalence, infectivity, etc., of this disease. The statistical region, as it might be called, has been very fully explored; but from the practitioner's point of view the much more important questions concerning recovery of movement and of function have been only lightly touched upon.

It cannot be a heresy to agree that rest and the prevention of deformities are vital parts of treatment, but at the same time to argue that these alone are insufficient to obtain the greatest possible amount of recovery of voluntary movement. It will possibly be stated that if muscles do not recover with rest and relaxation of opponents they will never recover at all. Also, if they do not recover, splints such as walking callipers, etc., will be necessary for the remainder of the patient's life.

This method of treatment has never completely satisfied me. I hate to see an individual permanently encumbered with a splint. When one is convinced that the acute inflammatory process has quite subsided—in many cases three months after the onset—a beginning should be made with the attempt to obtain re-education of the "apparently paralysed" muscles. Every effort should be made to obtain as much recovery as possible while the patient is

recumbent—that is to say, during the first twelve to twenty-four months. Recovery after this period, when the patient is up and about, is much more difficult.

These "apparently paralysed" muscles, although very responsive to proper methods of treatment, are exceedingly delicate structures, and if subjected to fatigue they rapidly waste and lose strength. This fatigue has to be carefully guarded against, and considerable skill is required to re-educate muscles satisfactorily. While fully aware of the danger of fatigue, the practitioner should always attempt muscle re-education (the principle of the minimal load), as without it the child has a definitely reduced chance of making a useful recovery.

I do not believe in the use of electricity in this disease, and I consider that the role of massage is very limited. —I am, etc.,

London, W.I., Nov. 20th.

CHARLES MACKAY.

Sir,—My experience as an orthopaedic surgeon brings me into daily contact with these cases. From the onset of the epidemic at Grays, and elsewhere in Essex, I have had the privilege of seeing, advising, and treating nearly all the patients, in consultation with Dr. Boul and other medical men.

As cases are still occurring, and now throughout England, I feel we cannot emphasize too strongly the following points: the deadliness of the disease, the importance of segregation and prophylaxis, the absolute necessity of prolonged treatment, and the very great risk of spreading the disease by the closing of boarding schools.—I am, etc.,

B. WHITCHURCH HOWELL, F.R.C.S.

London, W.I., Dec. 6th.

#### SURGERY IN GENERAL PRACTICE.

Sir,—I entirely agree with Sir James Berry. I am a Fellow of the College of Surgeons in general practice. For more than ten years I have given up all but minor surgery as a mute protest against what I see. When such operations as gastro-enterostomy and excision of the upper jaw are undertaken by general practitioners who do not perform a dozen major operations in a year, it is time that someone spoke out.—I am, etc.,

November 30th.

F.R.C.S.

Sir,—Sir James Berry does not appear to realize that many general practitioners who do major surgery and who are members of the staff of the hospital in the town in which they practise make considerable efforts to qualify themselves for the surgical work which they are called upon to perform.

Commencing their training whilst holding one or more house appointments at a big hospital, they supplement their knowledge and experience by taking out courses in operative surgery and by periodical visits to the operating theatres in London or other large centres, where they see the latest improvements in methods and technique.

The Fellowship of Medicine, in the development of which Sir Arbuthnot Lane has taken great interest, has, in recent years, enabled many men to pay these periodical visits under the most advantageous conditions.

As Dr. Gordon Taylor says, we general practitioner surgeons have to live among the people upon whom we operate, and if the results obtained were not sufficiently good, our colleagues would soon cease to ask us to operate on their patients, and our own patients would no longer ask us to operate upon them or on other members of their families.—I am, etc.,

December 6th.

M.D., F.R.C.S. (In general practice.)

Sir,—This appears to me to be another onslaught on the general practitioner, who has but recently survived the charges of being an incompetent obstetrician.

The general practitioner will not undertake that surgery which he knows he cannot accomplish. Moreover, the claims (to do surgery) of many men engaged in general practice are sometimes greater than those of some "half-baked specialists." Some of us have but recently taken to general practice and have probably done more surgery

than anything else; we cannot announce our claims to the local world as we take our place in the practitioner ranks, but we are thankful to get the opportunity of doing surgical work when it comes our way.

I have known a lady whose appendix was removed by a consulting surgeon "as a placebo." (He told me so.) I met her accidentally through the nurse sending for me (as an emergency) because the patient had a severe secondary haemorrhage in the region of a post-operation faecal fistula. I tied the artery and reported to the surgeon, who had been unable to come himself. Accidents will happen, but suppose this state of affairs had occurred to a general practitioner's case? He would probably cease doing appendicectomies! But do not these pronouncements from some of the consulting class, whether on surgery or on obstetrics, savour of an intolerable egotism?

The general practitioner is usually the unpaid agency through which many cases are introduced to the consultant. There are many consultants—surgeons and non-surgeons—whom it is not only a pleasure but an education for me as a general practitioner to meet professionally, and most men in general practice will endorse this view. But in every class, political or surgical, there are irritating extremists to be found.—I am, etc.,

Swansea, Dec. 4th.

L. W. HEFFERMAN.

### TEAM WORK IN A SMALL HOSPITAL.

SIR,—Your correspondents have already made a strong protest against the remarks of Sir James Berry severely criticizing the work of the operating general practitioner. My object in writing is to suggest a policy that will enable the operating practitioner to increase his usefulness and enlarge the scope of his activities. This policy has been adopted and is working well in a small provincial hospital of eighty beds. After the great war, when practically all the staff had served in France or the Far East, the advantage of team work was realized, and we tried to put our house in order. As five at least of the staff of ten honorary physicians and surgeons had acted as surgical specialists in the R.A.M.C., there was little difficulty in inaugurating a scheme of work.

The details of the arrangement are, briefly: Each member of the staff is to devote himself, in addition to his ordinary routine, to one special branch of surgery or medicine. We have therefore the following departments: (1) Diseases of children; (2) diseases of women; (3) nose, throat, and ear; (4) radiology and electro-therapeutics; (5) eye department; (6) venereal diseases; (7) pathological department; (8) urinary diseases; (9) orthopaedics.

Each member of the staff took the subject in which his inclination and previous experience enabled him to make a good beginning in the specialty of his choice. The municipal authorities have already recognized the value of the system by appointing those of the staff whose work justified the choice to do special obstetric, throat and ear, and eye work in connexion with school children and other activities of the medical officer of health. This happy arrangement has only been rendered possible by good feeling and professional enthusiasm in a body of men who take a pride in their local hospital.—I am, etc.,

Lowestoft, Dec. 6th.

H. MUIR EVANS.

### SANATORIUM TREATMENT.

SIR,—It is with diffidence that I again make use of your columns on this subject, but I think Dr. Clarke's letter (November 27th) calls for a reply.

I have been accused by Dr. Gillespie (October 30th) of "resorting to a controversial device"; whether I did misrepresent him as saying what he did not say I am content to let your readers decide, but I will reply to Dr. Clarke's points by a method which presumably I may be allowed to use without question, by producing statistical evidence, much of which can be found in the memoir itself.

1. Though it is true that the *mean* time before admission of the incipient group of patients to sanatorium was as stated by Dr. Clarke, 114 out of the 170 cases, or two-thirds, were admitted within six months, and 97, or 57 per

cent., within three months of their first visit and classification. In considering histories over a long period like six years the *mean* latent period gives an erroneous impression, since it is unduly increased by a very small group of cases admitted three, four, or five years after first coming under observation.

2. The progress of the 114 cases admitted within six months, 85 per cent. of whom were admitted within three months, has been separately assessed in Tables III to VII, and their progress shown to be apparently no better than those admitted after a longer delay or not at all. A considerable proportion of these cases (about 75 per cent.) were recommended for sanatorium immediately, on the basis of the first examination, allowing no opportunity for selection on the basis of progress such as Dr. Clarke postulates.

3. The possibility of such selection coming in, which he says we "appear to have forgotten," is, in fact, examined on p. 440 of the memoir by the most accurate method available for such purpose—namely, by measuring the fall in weight of adult patients subsequently chosen for sanatorium in the interval between first visit and admission. For incipient cases this fall in weight averaged about half a pound, as compared with a mean increase of about the same amount in those not chosen for sanatorium (over a similar period), and the conclusion was that "the average loss here is too small to be appreciable in influencing selection" (p. 440), and certainly too small to be responsible for any considerable differences in ultimate progress of the groups.

4. In case body-weight be objected to as an insufficient index of progress during the waiting period, my colleague Miss N. Karn has taken out the following figures for adult male patients, using the general assessment of progress employed in the memoir.

Percentage of Adult Male Patients Classified as "Stationary or Worse" amongst the Total Still Alive and Under Observation.

|                                     | During first 3 months. |            |            | During second 3 months. |
|-------------------------------------|------------------------|------------|------------|-------------------------|
|                                     | Li.                    | La.        | Li and La. | Li and La.              |
| Men subsequently sent to sanatorium | 59.1 ± 7.1             | 62.5 ± 4.5 | 62.2 ± 3.8 | 53.2 ± 3.8              |
| Men not so sent                     | 54.8 ± 6.2             | 64.9 ± 3.1 | 62.1 ± 2.6 | 55.6 ± 3.1              |

There are no significant differences here, and I think I have said enough to prove that the manner in which the patients were progressing between classification and selection for sanatorium was actually not a factor of much importance in that selection.

The question as to whether the "methods of reasoning" used in the memoir are "faulty" or otherwise can be safely left for experts in such matters to decide. One thing, however, is certain: if the ultimate curative value of sanatorium treatment for patients in the aggregate cannot be proved by statistical methods it cannot be proved at all. I would venture to suggest that a more convincing and useful form of argument than any of those which have been used would be the production of other figures which, to the satisfaction of experts, lead to a conclusion contrary to the one we have reached. It cannot be denied that the difficulties to be faced in such an inquiry are very considerable, but they are not insurmountable, and the issues involved are of sufficient magnitude to justify repeated attempts and the expenditure of much ingenuity and labour in an effort to reach the truth. If the present discussion has done anything to make clear the need for a repetition of this investigation by similar or improved methods on other municipal tuberculosis records, it will not have been fruitless. To throw doubt on the real curative efficacy of sanatoriums without being able to suggest a better substitute must be a task neither inspiring nor congenial, but to continue to leave in doubt a matter of such importance through lack of the courage or will to face it is a policy which will do us no credit.—I am, etc.,

PERCY STOCKS.

Galton Laboratory, University College, London.  
Nov. 28th.

### A MEDICAL ASPECT OF MINERS' SHORTER HOURS.

SIR,—The conclusion of Dr. G. Arbour Stephens, in his letter in the *BRITISH MEDICAL JOURNAL* of November 13th (p. 906), is that the nine-hour day is better for the miners than the seven-hour day, because it is less exhausting, enables food to be partaken of when underground, and lessens the "pace" of the work. Dr. Stephens claims that these factors, together with certain recent methods of working the coal, result in more colliers giving up day-work for piece-work on account of heart and nerve trouble at 50 years of age. Obviously, medical data are not forthcoming and need to be collected before his conclusions can be seriously considered.

There is, however, another medical aspect to shorter hours—namely, the number of accidents arising from industrial fatigue. The Labour Research Department in a circular of August, 1926 (p. 171), states that there are no properly analysed and comparative statistics of industrial fatigue for coal-mining. There is, however, clear general evidence that what matters is the cumulative strain of longer working hours. This shows itself in the reduction of the total number of accidents following on the reduction of hours in 1919. (See Mines Department Report below.)

There is shown to be a reduction in all accidents when the seven hours became operative. From 1922 onwards there has been a worsening of the miners' wages; their endurance has been weakened and the result has been more accidents. Both lower wages and longer hours lower the average physical condition.

*Accidents at All Mines.*

| Average.         | Fatal Accidents<br>per 100,000<br>Employed. | No. Serious-ly<br>Injured per 1,000<br>Employed. | No. Injured<br>per 1,000. |
|------------------|---|--|---------------------------|
| 1908-1912 ... .. | 136.3                                       | 5.6  | 145.6                     |
| 1913 ... ..      | 151.5                                       | 5.1  | 154.9                     |

| 1924 ... ..      | 97.7  | 4.0  | 158.2                     |

Figures for 1921 are not included as they were affected by the stoppage.—I am, etc.,

Plymouth, Nov. 20th.

F. G. BUSHNELL, M.D.

### THE THEORY OF DIAGNOSIS.

SIR,—Dr. F. G. Crookshank's Bradshaw Lecture, as reported in the *BRITISH MEDICAL JOURNAL* of November 20th (p. 955), bristles with interest. I see he states that Galen was himself largely "to blame" for the woodenness into which mediaeval Galenism lapsed; this will be news to many people, as I think it has been always understood that the fault lay essentially with Galen's successors.

But this by the way. Dr. Crookshank's address was mainly a brave plea for nominalism (or, more exactly, conceptualism à la William of Occam). In other words, it was a convincing attack on present-day entity-worship in medicine—on the dangerous tendency shown by our art to become dominated by words. There is one other point. Do those who agree with Dr. Crookshank's contention also realize how the danger is being added to by the growing bureaucratization of medicine, with its insistence on schedule-filling, "exact diagnosis," etc.? After all, is not this largely a psychological matter, and, if so, what have the psychologists to say about it?—I am, etc.,

North Queensferry, Fife, Nov. 23rd.

A. J. BROCK.

### APPENDICITIS AND VEGETARIANISM.

SIR,—Mr. Hamilton Bailey's letter in the *JOURNAL* of September 18th (p. 545) is of particular interest to those practising in India. In certain parts of India a fair proportion of the people is strictly vegetarian, and the occurrence of appendicitis among them is not an uncommon

thing, though not so common as in Western countries. During the last two months I have operated upon two cases of recurrent appendicitis, and both the patients were lifelong vegetarians.—I am, etc.,

Sadia, India, Oct. 18th

D. D. VARIAVA, F.R.C.S. Edin.

SIR,—The infrequency of appendicitis among natives of India, to which further reference was made in your issue of December 4th, is undoubtedly a very definite fact. On several occasions on which I held charge of surgical work among Indian troops I was struck by the quiescence of their appendixes. I have seen one or two cases among Gurkhas, who are certainly Northerners though hardly Indians; but during one appointment, lasting over twelve months, as surgical specialist for Indian troops, Rawalpindi Divisional Area, I did not find cause to remove a single appendix.

In my experience the immunity, as far as army personnel is concerned, appears to fall fairly evenly on all natives, although the martial Northern races naturally come under wider review.—I am, etc.,

London, N.W.3, Dec. 5th.

B. FRASER BEATSON,  
Major, late I.M.S.

### Obituary.

DR. LIONEL WYKHAM HAYWARD, who died at Adelaide, on September 12th, aged 45, was the second son of Colonel W. T. Hayward, C.M.G., LL.D., at one time chairman of the Australian Federal Committee, and well known to many members of the British Medical Association in England. He was educated at St. Peter's College, and graduated M.B., B.S. of the University of Adelaide. After practising for some time at Port Adelaide his health broke down, and he went up country to Loxton, where he became closely associated with the tuberculosis sanatoriums at Bedford Park and Myrtle Bank. He took an active part in the founding of the Tubercular Soldiers' Association in 1920, and until the time of his death remained closely connected with it. Dr. Lionel Hayward was a strong advocate of the provision of permanent pensions for this disability and a keen supporter of preventive work, particularly among the young. Like his father he was a member of the South Australian Branch of the British Medical Association. His brother, Dr. Lancelot Hayward, is in practice at Perth, Western Australia.

DR. FREDERICK HARRISON TETLEY died on October 4th at the age of 74. He received his medical education at Glasgow, and obtained the L.R.C.P. and L.R.C.S. Ed. diplomas in 1877. He practised in Bungay for ten years, during which time he was surgeon, and later, consulting surgeon, to All Hallows Hospital, Ditchingham. In consequence of the failing health of his wife he gave up that practice in 1901, and for ten years spent the winters abroad, chiefly in Las Palmas, where he continued to practise and served as honorary surgeon to the Victoria Hospital to Seamen. He then retired from practice and devoted himself to travelling until the onset of the war, when he resumed his medical work, and for eighteen months carried on the practice of Dr. T. L. Ingram at Walford, near Rugby. After the death of Dr. Ingram, who was killed in action in 1916, Dr. Tetley was appointed surgeon to the Guards at Caterham, and subsequently became physician to the City of London Hospital at Epsom, where he contracted typhus, which affected his health for some years. He also acted as chairman of medical boards in various parts of the country, and after the war served in the same capacity on pensions boards at Portsmouth, Dover, and elsewhere.

DR. WALTER ERNEST FRY, who died on November 11th, after a short illness, was born in 1869, and received his medical education at the London Hospital, obtaining the diplomas M.R.C.S., L.R.C.P. in 1893, and the D.P.H. in 1909. After experience as clinical assistant in the medical and ear departments of the London Hospital, resident clinical assistant to the Queen's Hospital for Children, and clinical assistant to the medical department of the West

London Hospital, he practised in Hammersmith, where he served as medical officer to the infant welfare centre since its commencement in 1911. He was surgeon to the throat and ear department of the London County Council school clinic, surgeon to the Parkside Maternity Hospital, medical officer to the Hammersmith school for mothers, and honorary secretary of the Hammersmith District Nursing Association; he had also acted as honorary secretary to the West London Medico-Chirurgical Society. For many years he gave active support to the British Medical Association, and was a member of the Metropolitan Counties Branch Council from 1913 to 1919, and again in the present year; he was vice-president of the Branch in 1921. From 1913 to 1919 he was honorary secretary and treasurer of the Kensington Division, and chairman from 1922 to 1925. Dr. Fry was a deputy representative from 1921 to 1925. He leaves a widow, one son, and two daughters.

Dr. C. J. LINTON PALMER of Stoke House, Gosport, who died on November 12th, aged 54, from pneumonia, was educated at University College, Liverpool, and took the diplomas of the English Conjoint Board in 1898. He served as resident medical officer at the City Hospital for Infectious Diseases, Parkhill, Liverpool, and later became resident medical officer to the lock, eye, and ear department and house-surgeon of the Liverpool Royal Infirmary. He removed to Gosport just before the war, and when hostilities broke out he became civil medical practitioner in charge of troops in the Gosport district. He subsequently took a temporary commission in the R.A.M.C., and served on the small hospital ships plying between Dover and Boulogne. Dr. Palmer was a member of the Portsmouth Division of the British Medical Association. He is survived by his widow and two children. The funeral service was attended by a large congregation representing all sections of the community.

Dr. RICHARD JONES OWEN, formerly of the Army Medical Department, died in London on November 17th, aged 87. He was the son of Dr. Owen Owen, took the M.R.C.S. and L.S.A. in 1861, and entered the army as assistant surgeon on March 31st, 1862, serving in the Royal Artillery, but resigned his commission on December 1st, 1865, over sixty years ago. He subsequently went to Australia, where he was in practice at Ballarat, Victoria, the famous goldfield for several years, and surgeon to the Ballarat Hospital; but retired from practice long ago. His name disappeared from the *Medical Directory* in 1883.

Dr. JAMES DOIG McCrindle, who died at his residence in Northampton on November 19th, at the age of 53, received his medical education at Edinburgh University and Guy's Hospital. He graduated M.B., C.M. Edin. in 1896, and obtained the D.P.H.Camb. in 1901. In 1897 he was appointed resident medical officer of the Birmingham City Hospital for Infectious Diseases, and held similar appointments at Nottingham from 1898 to 1900, and at Croydon from 1900 to 1902; at the latter place he was also bacteriologist and deputy medical officer of health. He was appointed medical superintendent of the Birmingham City Small-pox Hospital in 1902, and two years later became assistant medical officer of health. In 1907 he went to Northampton as medical officer of health, which post he held until his death. He was a prime mover in the establishment of the Creton Sanatorium, which was built by voluntary subscription in 1910, and he remained an active member of the executive committee of this institution. He was a member of the South Midland Branch Council of the British Medical Association.

Mr. EDWIN WEISE COATHUPE, who died on November 23rd at Boscombe, was born as long ago as 1837. After studying medicine in the medical school and Royal Infirmary at Bristol, he obtained the diploma of M.R.C.S. in 1859. He was then appointed assistant surgeon to the Tredegar Iron Works, but, three years later, gave up

medical practice and was appointed to the detective branch of the Metropolitan Police, which at that time consisted of two inspectors and ten sergeants. After three years' service in London he returned to Tredegar as chief surgeon, but a year later resigned this appointment in order to become chief constable of Manchester at the time of the Fenian outrages. In 1876 he was chosen out of 122 candidates as chief constable of Bristol, an office which he held until 1894. After his retirement he lived abroad for some years, principally in Rome. During his period of office at Bristol the police force there doubled in size and was entirely remodelled. In accordance with his suggestion the city was divided into divisions, the rank of superintendent created, and the police fire brigade and the river police were established. He also introduced the general use of police vans, and was responsible for a great advance in the reputation of the police system in Bristol; many men trained by him obtained high positions in various parts of the country. At his retirement he was presented with an address and a cheque by the Bristol justices. We know of no other instance of a medical man quitting the practice of his profession for service in the police force and becoming a chief constable.

Dr. ALEXANDER LAWRENCE died at Chester on November 23rd, aged 81 years. He was born at Cullen, Banffshire, in 1845, and was educated at Aberdeen University, where he graduated M.A. in 1866, M.B., C.M. in 1869, and M.D. in 1872. After serving as clinical clerk to the West Riding Asylum, Wakefield, and superintendent of Chalmers Hospital, Banff, he became second assistant medical officer to the County Asylum, Chester, in 1870, and twenty-five years later succeeded Dr. Davidson as medical superintendent. In June, 1910, he retired on superannuation, when a presentation was made to him by the asylum visiting committee and staff. He was for many years a member of the Chester Society of Natural Science, and of the Chester Division of the British Medical Association.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on November 27th the following medical degrees were conferred:

M.B., B.Chir.—H. Corsi, H. R. Youngman.

The number of medical students in the University this term is 457. Of these 163 are in their first year, 142 in their second, and 115 in their third year; there are 26 fourth-year medical students, and 11 in their fifth or later years.

### UNIVERSITY OF LONDON.

The Paul Philip Reitlinger Prize, offered this year for the best essay embodying the result of some research work on a medical subject carried out by the candidate, has been awarded to William Stewart Duke Elder, M.A., M.D., F.R.C.S., who is now working at University College, London, for his essay on "The ocular circulation: its normal pressure relationships and their physiological significance." Next year the prize will be awarded for the best essay on "The nature of belief and its place in human experience."

The following candidates have been approved at the examination indicated:

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—(With special knowledge of Psychiatry): R. G. Anderson, D. H. Cameron, H. Harris. (With special knowledge of Mental Deiciency): R. M. Macfarlane.

### UNIVERSITY OF BIRMINGHAM.

Dr. OSCAR BRENNER has been appointed part-time assistant and Mr. Cecil C. Harries assistant to the Department of Pathology and Bacteriology.

Professor G. Elliot Smith, M.D., F.R.S., will deliver the Huxley Lecture in the medical theatre of the University on February 1st, 1927, at 5.30 p.m.

### UNIVERSITY OF EDINBURGH.

The following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—H. El S. Abaza, J. du R. Ackermann, A. Ahmed, J. B. Annau, T. W. Banks, F. W. Clark, A. R. Cowan, I. R. Duthie, V. Dyrean, W. D. Forsyth, E. H. Griffiths, Euphemia T. Guild, Janet W. Jackson, Eva G. John, Isabella M. Marshall, E. P. L. Mas-on, W. H. Moore, Katherine M. Muirhead, K. B. Mukerjee, G. Nahapiet, J. G. Paul, M. R. J. Peters, F. W. Pringle, W. H. Ross, Janet C. Ronaldson, Roma M. Ross, G. A. Rylie, J. Singh, Marie Steven, E. Sutherland, Winifred E. Wall, Marjorie S. Waterston.

## UNIVERSITY OF ABERDEEN.

The Munday Prize in the Faculty of Medicine has been awarded to Frances E. Bruce and John H. Otty (equal) and the Venn Prize in the same Faculty to Brennan S. Craun and Art. Jane F. Emmanuel (equal).

Prof. or Marnoch has been appointed and Professor Mackintosh reappointed assessor to the University Court, the former for the period to November, 1928, in succession to Professor Matthew Hay, and the latter for the period to November, 1930.

UNIVERSITY OF DUBLIN.  
SCHOOL OF PHYSIC, TRINITY COLLEGE.

F. W. PIENAR has been approved for the degree of Master in Obstetric Science (M.A.O.).

The following candidates have been approved in Part II of the Final Medical Examination:

M.B.—E. G. Montgomery, Margaret H. Donaldson, E. P. N. M. Farly, J. C. T. Sanctuary, M. L. M. Canley, S. Margaret E. Deane-Oliver, J. B. Patrick, D. Blomitt, Rachel E. Port-r, J. J. FitzGerald, R. Kahn, S. Gurevich, J. O. Bennett, H. A. Ferguson, R. A. J. Holmes-Lavers, J. Quigley, G. D. Edwards, C. F. M. Wilson, M. Hoffman, Kathleen R. Byrne.

B.Ch.—V. St G. Vaughan, L. B. Somerville-Large, E. H. Harte, V. G. Horan, A. J. Conlin, Stella C. Ross, Annette E. Wood-Martin, E. P. N. M. Farly, D. W. Bingham, E. G. Montgomery, A. S. B. Odbert, Norma M. Smith, A. H. Gray, A. E. A. O'Brien, J. B. Patrick, D. A. O'Connell, D. A. Ellis, Rachel E. Port-r, W. P. Knobel, Gladys L. Craig, J. Johnston, J. A. O'Dwyer, C. F. M. Wilson.

B.A.O.—W. F. Lane, L. B. S. MacFarlane, R. S. P. Hennessey, T. C. M. Corbet, S. D. K. Roberts, Wilfred D. C. T. Pigott, G. M. Smith, J. Jeanson, P. Branigan, G. H. Henry, J. H. Stephens, M. F. N. Griffin, C. L. Day, Christina McDonald, Ethel M. Weir, L. E. Brumberg, H. C. Weir, G. McDonald, S. R. Fines, D. M. Brink, A. Sachs, T. J. O'Reilly, J. O. Bennett, A. C. C. Charles, S. B. Dalrymple, Norma W. Brown, C. F. Cope.

\* Passed on high marks.

## ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

The annual meeting of the Royal College of Physicians of Edinburgh was held on December 2nd. Dr. George M. Robertson was re-elected President for the ensuing year; Sir Robert Philip was nominated Vice-President; Drs. G. Lovell Gulland, R. A. Fleming, Robert Thin, John Orr, and Edwin Matthew were re-elected to form the Council.

At an extraordinary meeting held the same day Drs. Edward Arnold Carmichael and John Robert Lord, C.B.E., were elected Fellows of the College. Drs. William Russell and John Orr were elected representatives on the board of management of the Royal Infirmary of Edinburgh.

## ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the monthly business meeting of the College on December 3rd the President duly admitted to the Licences in Medicine and Midwifery the following successful candidates at the Winter Final Examination under the Conjoint Scheme with the Royal College of Surgeons in Ireland:

D. P. P. Barry, J. J. Lee, P. H. M. McEntee.

## The Services.

## MEDICAL DIRECTOR-GENERAL, R.N.

UNDER revised regulations for the retirement of officers, the Medical Director-General of the Royal Navy is to be retired on ceasing to hold the appointment, or, if not previously superseded in the appointment, to vacate it and be retired on attaining the age of 65.

## DEATHS IN THE SERVICES.

Surgeon Commander William Henry Daw, R.N. (ret.), died at Lydford on November 14th. He was educated at the London Hospital, where he was scholar in practical anatomy in 1891; after taking the M.R.C.S., the L.R.C.P. Lond., and the L.S.A. in 1895, he served successively as house-surgeon at the London Hospital, house-physician and resident medical officer at the Royal Hospital for Diseases of the Chest, and surgeon to the Royal National Mission to Deep Sea Fishermen; afterwards he entered the navy as surgeon. He attained the rank of surgeon commander in 1912, and retired some six years ago. He was the author of a small work, *The Care of Consumption*, and of the articles on adenoids and cruetism in *The Complete System of Nursing*.

Colonel Denis Moriarty O'Callaghan, C.M.G., Army Medical Service (ret.), died at Budleigh Salterton on November 6th, aged 64. He was the youngest son of the late Robert O'Callaghan, L.L.D., of Holton, Suffolk. He was educated at Queen's College, Cork, and at the Carmichael School, Dublin, and took the L.R.C.S.I. in 1884 and the L.K.Q.C.P. in 1885. He entered the army as surgeon on July 28th, 1886, was gazetted colonel in the long war promotion list of March 1st, 1915, and retired on November 11th, 1918. He had a long list of war services: Ashanti expedition, 1895-96 (star); Nile campaign of 1898, battle of Khartoum, mentioned in dispatches in the *London Gazette* of September 30th, 1898 (medal, Egyptian medal with clasp); South African war, 1900-01, operations in Orange River Colony, including action at Wittebergen, and in Cape Colony (Queen's medal with three clasps); war of 1914-18, mentioned in dispatches four times, and received the C.M.G. on June 3rd, 1917.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The principal debate in the House of Commons this week was on the vote of censure moved by the Labour party on December 8th, which challenged the conduct of the Government during the coal dispute. The official end of that dispute was marked on December 10th by the submission to the House of a resolution approving the cancellation of the Emergency Regulations.

On December 6th the Housing (Rural Workers) Bill, the Public Health (Smoke Abatement) Bill, and the Prisons (Scotland) Bill were passed through Report and third reading by the House of Commons. On December 7th the University of London Bill was read a third time and passed, and several small bills were advanced. Thursday and Friday were assigned to the remaining stages of the Judicial Proceedings (Regulation of Reports) Bill, the purpose of which is to prevent full reports of divorce cases where publication may do harm.

In the House of Lords the Workmen's Compensation (No. 2) Bill passed through Report on December 6th. The Births and Deaths Registration Bill was read a second time on December 7th.

The Coroners Bill was considered in a Standing Committee of the House of Commons on December 7th, and was set down again for December 8th.

## Housing Subsidy.

In the House of Commons, on December 2nd, Mr. Neville Chamberlain moved a resolution approving the draft order of the Minister of Health and of the Scottish Board of Health (presented on November 25th) which proposed to reduce the housing subsidy after next September by £2 in the £6 annual subsidy for twenty years under the 1923 scheme, and by £1 10s. in the £9 subsidy for forty years under the 1924 scheme. So long as it was understood that the subsidy would continue to be paid until the demand for houses was satisfied or until the price fell, there would be no fall in the price of houses. Mr. Wheatley said that national interest demanded healthy housing for the working class. The needs of London were estimated at 72,000 houses. Manchester still required 46,000 houses, and Liverpool had a waiting list of 20,000 applicants, every one of whom had at least two children. The case of Birmingham was equally bad. Leeds had 33,000 back-to-back houses, which it could not demolish till there were houses for the displaced population. He opposed the motion. Lord Henry Cavendish-Bentinck said Nottingham had 4,000 applicants on its waiting list and 3,000 houses unfit for human habitation. In Middlesbrough, of 1,679 tuberculous patients on the register, 486 were sleeping in beds along with persons who were not tuberculous. There were 220 houses each occupied by two families, and in each one family had tuberculous patients. In Birmingham Sir John Robertson reported that he had investigated a group of 527 houses, of which 130 were uninhabitable. Mr. Charleton said that in Leeds health corresponded exactly with the district of residence. Mr. Harris said that in London the pressure on housing had been as great during the last twelve months as in the year before. In the past year the London County Council had received 120,000 personal or written applications for housing accommodation. The L.C.C. list had been closed for some months. Mr. Montague said the nation was paying £80,000,000 to £86,000,000 annually for social services, and a great part of that expenditure was due to the bad health and inefficiency which came from overcrowding and bad housing. Mr. Gibbins said that in Liverpool houses which had long been condemned were still occupied by three or four families. Commander Kenworthy spoke of visiting houses in Hull, a hundred years old, with only one water-tap in a yard shared between twenty houses and with disgraceful sanitary arrangements. Dr. Baden Guest said that the arrears in normal housing had not been overtaken; housing was a living nightmare for the people. Mr. Greenwood said a large proportion of the Addison houses were occupied by bank clerks and professional people because the rents were too high for working-class people to pay. The rents of municipal houses were too high. In Nottingham, out of 4,500 applicants for houses, 1,300 wished to move from corporation houses into smaller and worse houses because they would be cheaper. Dr. Fremantle had made an estimate, which had never been refuted, that the annual cost of sickness to this country was £150,000,000, and Mr. Greenwood asserted that sum to be spent largely through the housing conditions. The late Mr. C. P. Child, in his presidential address to the British Medical Association, had said the country could spend without loss £50,000,000 annually in clearing slum areas if thereby the cost of sickness and disablement were reduced by a third. Sir Kingsley Wood said that it was vital to the poorer members of the community that the cost of building should be reduced. Of 768,000 new houses built in this country since the war, nearly half had been completed in the last two years. The indications were that during the next twelve months the 200,000 mark would be passed. A Labour amendment was defeated; and Mr. Chamberlain's motion was carried by 181 to 111.

*Rural Housing.*

In the House of Commons, on December 6th, the Housing (Rural Workers) Bill was considered on the Report stage. Mr. C. Edwards, the Labour member for Bedwellty, moved an amendment providing that no assistance should be given for the repair of a house unless the local authority was satisfied that the house, when altered, would contain a fixed bath and that the walls or other partitions of the bedrooms would comply with the requirements of decency. Mr. Chamberlain, Minister of Health, resisted the amendment. He pointed out that in the Act of 1923 as amended by that of 1924, discretion was given to the Minister with regard to the provision of a fixed bath "in a bathroom." The amendment would give no discretion. If it were carried either a large number of proposals would be scrapped because the owners would not undertake the additional expense, or the fixed bath in a bathroom would be provided at the expense of some other alteration or improvement. In reply to further questions, Mr. Chamberlain said that he would consider whether he should issue a circular to the local authorities expressing an opinion that it was desirable to have a fixed bath in the houses. The amendment was defeated, and the bill was read a third time.

**University of London Bill.**

The London University Bill was passed through Standing Committee on December 2nd. Lord Eustace Percy (Minister of Education), in discussing its provisions, said a strong memorial, signed by many teachers of the University, pressed for the passage of the bill in the present session, but made one proviso—that the Government should make it clear that the Statutory Commission would have power to consider how the relations of the Council to the Senate should be defined in case of difference of opinion between the two bodies. He did not, however, see how any deadlock could arise, because questions of pure detail within particular university departments would not be dealt with by the Council, but by the Senate; but if the Statutory Commissioners, having laid down the lines of the Council, and having defined that the Council should have final authority in the allocation of the funds, should have final authority in the matter that still there might be a danger of a deadlock.

On Clause 4, relating to powers and duties of commissioners, an amendment requiring the commissioners, in framing statutes, to give effect to a number of directions for the constitution of the Senate and its standing committees, as set out in a tabled amendment to the schedule, was negatived.

A new clause making provision as to the appointment by the Crown of members of a council of the University was added to the bill. The bill was read a third time by the House on December 7th.

**Insurance Benefits.**

Mr. Chamberlain has stated, in answer to questions, that the amounts of sickness and disablement benefits paid to members of approved societies during the first nine months of 1925 and of 1926 could not be given, these figures only being returned for calendar years. From January 1st to September 30th, 1925, £13,046,000 was issued from the National Health Insurance Fund to approved societies in England and Wales to defray the cost of benefits and administration, and for the corresponding period in 1926 £15,740,000. During the same period of 1925 the income from contributions in England and Wales was £18,321,000, and the State contribution was £5,489,000. For the first nine months in 1926 the respective figures were £16,368,000 and £4,725,000.

Mr. Chamberlain told Colonel Applin that the new scale of fees for dental treatment had not been laid down by regulations, but had been reached by agreement between representatives of approved societies and the dental profession. A few societies had not adopted the scale. If it became clear that the adoption of the scale by a society was essential to the provision of a satisfactory service he would take the necessary steps.

The Minister of Health has decided, in view of the coal stoppage and consequent unemployment in various trades, that arrears of contributions under the National Health Insurance Act might be accepted up to January 31st, 1927, in cases where a society was satisfied that the delay in discharging arrears was due to financial difficulty arising out of the industrial situation. This decision was being conveyed to all approved societies.

*Sickness Benefit.*

Mr. Chamberlain stated, on December 6th, that the total amount of sickness and disablement benefit paid in 1925 to contributors to the National Health Insurance schemes in England and Wales, during periods of illness which rendered the contributors incapable of work, was, approximately, £13,849,000. It was estimated that the total number of weeks of sickness represented by this payment was upwards of 25,000,000. In making this estimate account had to be taken of a number of uncertain factors, and the result could only be regarded as a rough approximation.

In reply to another question, he said that it was an essential feature of the National Health Insurance Act that money payable by way of benefit should not be diverted to Poor Law authorities or otherwise used to relieve local rates. Benefit was not assignable.

*Dental Benefit.*

In an answer to Mr. Rhys Davies, Sir K. Wood said the new agreement on the scale of charges and conditions of service for the dental treatment of members of approved societies was arrived at by direct negotiation between representatives of the societies and of the dental profession. It involved some increased charge on the surplus funds of societies above that which would have arisen under the scale previously in operation, but the great majority of societies thought the additional advantages to be

secured under the new arrangement justified the extra cost. A few societies had not yet decided to adopt the new scale, but the Minister of Health did not think that the position called for any special action on his part at present. There was no reason to apprehend that the other societies, representing about 80 per cent. of the total, were likely to alter the existing arrangements, to which their representatives had agreed.

Mr. Blundell asked whether Sir K. Wood was aware that the dentists were following in the footsteps of the doctors. He asserted that unless some steps were taken they might in very many cases obtain remuneration out of proportion to the services they rendered. Sir K. Wood replied that approved societies and members of the dental profession both thought they had made a bad bargain. Consequently he inclined to think this a fair arrangement.

Replying to Mr. Rhys Davies in writing, Mr. Chamberlain said the number of claims for dental and other treatment benefits in proportion to membership undoubtedly varied between the different approved societies, but he had no evidence that this was to be explained by the failure on the part of some societies to carry out the requirement that they should send notice to all their members of the additional benefits provided. He did not think it necessary to inquire of every society as to the manner in which this requirement was carried out.

**Mental Deficiency Bill.**

The Mental Deficiency Bill came before a Standing Committee on December 7th. On the motion of Dr. Vernon Davies the word "strong" was omitted from the definition of "moral defective" as a "person in whose case there exists mental defectiveness coupled with strong vicious or criminal propensities." Mr. Chamberlain said he could accept the amendment, and Dr. Fremantle supported it, saying that to define mental deficiency was most difficult. The amendment was carried.

Mr. Atkinson called attention to the fact that there were no words in the definition of mental deficiency which would cover cases of encephalitis lethargica in an adult. The definition was limited to "arrested or incomplete development of mind." He moved to add "mental disturbance" to cover cases where the mind was deranged by disease after full development. Mr. Chamberlain said the Board of Control had never heard of moral imbecility following encephalitis lethargica in an adult. The exclusion of adults from this bill was deliberate, and even if cases of such sequels occurred in adults they should still be excluded. The colonies contemplated by the bill were only suitable for young persons. At present adults could only be dealt with as lunatics. Dr. Fremantle said the separate system of dealing with mental deficiency in young persons had been deliberately built up—something quite distinct from mental hospitals—but the ordinary law of lunacy should be developed to allow of more treatment in mental hospitals. The number of institutions available for mental defectives in the ordinary sense was inadequate and should not be employed for adults. Answering a question, Mr. Chamberlain said he was informed that the maximum age at which mental development was completed was 25. Dr. Fremantle pointed out that the structure of the mind was deemed to be completed at 17 to 21. Mr. Atkinson's amendment was defeated. Dr. Vernon Davies moved similar amendments to extend the bill to "perverted" development of mind at any age as well as "arrested" development. Mr. Chamberlain said the addition of "perverted" would include adults, and he could not accept it. The Committee supported Mr. Chamberlain. In reply to Mr. R. Morrison, Mr. Chamberlain said that the original definition of mental deficiency had proved too narrow. It was now recognized that mental deficiency need not be innate. Causes beside disease and injury might subsequently be recognized, and elasticity should be allowed lest unfortunate persons should be deprived of the protection of the bill. After some remarks by Dr. V. Davies the motion was not pressed. The Committee accepted an amendment by Mr. Chamberlain to make plain that the bill allowed mental defectives to be placed under supervision or guardianship or sent to an institution. Mr. Atkinson moved that three years should be substituted for five as the period during which the mental defective could be detained in an institution without re-examination. Mr. Chamberlain said that with the doubtful case of encephalitis lethargica there was scarcely any prospect of improvement in three years. The Board of Control would inspect the institutions twice a year and had absolute power to discharge at any time children thought to be cured. Dr. Davies said the investigations of the Royal Commission showed that no cases of illegal detention could arise. Mr. Chamberlain reminded the Committee that the first detention was for one year, not for five. There was no danger of cases of improvement being overlooked. Mr. Atkinson's amendment was defeated. The same member then moved that the Board should see that the mental defective was informed of his right to be examined by an independent doctor. Mr. Chamberlain gave a pledge that this would be done administratively. Sir Kingsley Wood moved to extend the safeguards of the bill to mental defectives placed in an institution by a parent or guardian. The Committee agreed. Dr. Davies moved that examination should be separately made by two medical men. He did this to protect medical men, who were nervous of these cases, fearing that they would be sued for damages. Mr. Chamberlain pointed out that the examination referred to in the bill was only of persons absent from an institution. The amendment was defeated. The Committee agreed to a proposal to authorize the local authorities to provide "occupation" where mental defectives could not benefit by "training," and consequential amendments were made. In reply to Mr. Tom Williams, Mr. Chamberlain said that only a small proportion of counties had provided institutions for mental defectives, but some had made arrange-

ments for the reception of children in other ways. The deficiency was serious, and pressure was being exerted on the county councils to provide institutions. After further minor amendments the bill was reported to the House.

### Smoke Abatement Bill.

The House of Commons, on December 1st, commenced to consider the Public Health (Smoke Abatement) Bill as amended in Committee. Mr. Scurr said the bill was in many ways admirable. An agreement had been made for exempting certain processes in Sheffield, but there was no justification for giving the Minister power, as the bill did, to exempt other industrial processes. When consideration of the bill was resumed on December 6th Mr. Scurr's amendment was defeated. Rear-Admiral Beamish moved an amendment to bring within the scope of the bill the chimneys of domestic dwelling-houses in London. It was high time to make the same effort in regard to smoke as had been made in regard to drains. Sir A. Holbrook seconded the amendment.

Mr. Chamberlain said that the amendment would apply only to London and would deal, not with new houses only, but with all houses, and was therefore quite impracticable on account of the cost. A further difficulty was that there would not be enough gas and electricity to go round. The amendment was negatived.

Sir A. Holbrook moved to include private dwelling-houses in Clause 5, which gives the urban authorities power to make by-laws requiring the provision in new buildings of such arrangements for heating or cooking as were calculated to prevent or reduce the emission of smoke. The motion was supported by Mr. Hardie.

Dr. Haden Guest said that the effect of the exclusion of houses would be that the smoke trouble would not be abated for a very long time. The direct effect of smoke was to cause a large increase in certain respiratory and other diseases. The indirect effect of smoke, especially in London and the greater towns, by cutting off the rays of the sun, was to produce disease of a rather different character, not directly respiratory. These two factors alone, if it were possible to abolish smoke at an early date, would increase the health and efficiency of the country to such an extent as would make a substantial reduction in the amount of money actually paid in sickness insurance, for hospitals, and in other ways.

Mr. Chamberlain said that while it was perfectly true that domestic smoke was responsible for much more of the smoke nuisance than industrial smoke, yet that smoke was produced by the chimneys of some 8,500,000 existing houses in the country. The amendment only applied to new houses. It might be assumed that the number of new houses erected by local authorities provided for the methods which they desired to be employed in them, while a large number of houses erected by private enterprise were fitted with exactly the same appliances. Therefore only a trifling number of houses a year could possibly be affected by the amendment. It was not the function of the bill to provide research was devoting its attention and spending a substantial portion of money in investigating this subject. If a certain proportion of houses now built by private enterprise had the open fire instead of the gas fire, it was because the people who inhabited them desired it, and he was not prepared to deny it to them until there was a reasonably cheap, economic, and satisfactory alternative.

The amendment was rejected by a majority of 138. On the motion of Lieutenant-Commander Astbury, the coming into operation of the bill was postponed from January 1st to July 1st next.

The bill was afterwards read the third time.

### Lead Paint Bill.

Mr. Rhys Davies asked the Home Secretary why the chief medical officer of the Factories Department, the senior medical inspector of factories, having reached the pensionable age, applied to be allowed to retire, giving as his reason that he did not wish to be concerned in the administration of the Lead Paint (Prohibition of Poisoning) Bill, and his application had been granted. Mr. Rhys Davies asked whether the resignation was not mostly due to the fact that the chief medical officer was not having carefully negotiated the Convention was adopted, and that in question. The Home Secretary replied: I do not know about his honour. He had reached a pensionable age. He did retire because he did not agree with the views which I have taken and the Government has taken with regard to the matter. I am expressing no opinion on the resignation. He could have served another couple of years possibly. He is quite entitled, if he desires, to resign his position, which he has done.

**Infantile Paralysis.**—On December 6th Sir Kingsley Wood told Colonel Gielton that no further cases of infantile paralysis had been notified in Rutland since the occurrence of two cases at Uppingham School during the week ended November 13th. In the present state of knowledge of this disease it was the practice of the Ministry of Health to recommend that patients who had been attacked by it should be isolated for six weeks from the onset of the disease. Asked how many cases of encephalomyelitis had been reported during the last six weeks, Mr. Chamberlain answered that encephalomyelitis was a generic term including conditions due to a variety of causes, some of which were not notifiable.

**The General Medical Council.**—Lord Sandon asked Major Hennessey, as representing the Lord President of the Council, whether the Lord President would select a non-professional member to fill the vacancy in the General Medical Council in January, and when his name would be announced. Major Hennessey said it was impossible to say in advance what action the Lord President might see fit to take when the occasion arose for filling this vacancy. Lord Sandon asked whether this meant that there was no parliamentary control in the matter. No answer was returned.

**Experiments on Animals.**—In an answer to Captain A. Evans, the Home Secretary said 1,059 vivisection licences were in force. Only one class of licence was issued. Particulars of the different certificates required for certain experiments were issued in the Home Office annual return. Mr. Macquisten asked whether there was any indication of whence the investigators obtained dogs and whether the animals were stolen or not. The Home Secretary said there was no indication. Captain Evans asked whether there were only two vivisection inspectors for the whole of Great Britain, and whether the Home Secretary would consider increasing the number. The Home Secretary said there was a strong tendency against such increases. One laboratory was visited thirty-five times in the last eighteen months, thirty times without notice, which showed the inspectors were doing their work well. In a further reply to Sir Robert Gower, the Home Secretary said he could not give reliable information on the number of dogs reported to the Metropolitan Police as missing or stolen during the past twelve months. Many owners did not notify the police. Hacking (Under Secretary of the Home Office) stated that since January 1st 823 dogs had been used for experimental purposes in premises within the London area which were registered under the Act. All but a very few of the animals were kept under complete anaesthesia during the whole time of the experiment and were destroyed before recovering from the anaesthesia.

**Orthopaedic Treatment of Children.**—In a reply to Mr. Gardner, Mr. Chamberlain said that orthopaedic treatment was provided for children of all ages suffering from surgical tuberculosis by the county and county borough councils under their schemes for the institutional treatment of tuberculosis, and for non-tuberculous crippled children under school age by the local authorities responsible for the maternity and child welfare service. It was open to the local education authorities to provide orthopaedic treatment for non-tuberculous children of school age in accordance with arrangements sanctioned by the Board of Education. An Exchequer grant was available in aid of these services amounting to 50 per cent. of the approved expenditure of the local authorities.

**Medical Attendance under the Insurance System.**—Mr. Chamberlain states that few specific complaints are received by the Ministry of Health regarding the medical attention afforded to panel patients, and nothing has come to his notice since the publication of the Report of the Royal Commission on National Health Insurance which would justify any further inquiry. The Royal Commission exhaustively investigated the efficiency of the medical service under the National Health Insurance Acts, and its report contained a very favourable verdict. He had received no report from the Kent Insurance Committee containing certain complaints in this matter.

**Opium in India.**—On December 6th Mr. C. Wilson asked whether, as a result of the Government of India's decision to reduce by 10 per cent. per annum the export of opium except for medical and scientific purposes, the imports into British dependencies in the Far East would be proportionately reduced; and whether an assurance could be given that opium for purposes of smoking would not be imported from other sources to compensate for the reduction in the imports from India. Mr. Amery said no such reduction would, in his opinion, be practicable at present.

**Research Stations in Palestine and East Africa.**—During the debate in Committee of the House of Commons on December 1st, when the Palestine and East Africa loans guarantee was considered, Mr. Ormsby-Gore, for the Colonial Office, said the reason why only a small proportion of the loan was set aside for research was that the Treasury would only give money out of loan funds for capital expenditure in connexion with research. Money would be forthcoming for any further capital re-equipment of the Amari Institute (East Africa), which would be turned into a first-rate scientific research institute, a link in the proposed chain of tropical research stations, of which Trinidad was the first.

### Notes in Brief.

Mr. Chamberlain hopes that the report of the committee investigating cases of encephalitis directly following vaccination will be published before long.

The number of pensions awarded to widows in England, Scotland, and Wales is 170,459. These include allowances for 269,100 children. Pensions have been awarded to 15,180 orphans.

The Minister of Health does not propose, as at present advised, to take any action concerning the Foundling Hospital site, as the question of its uses will come before Parliament on a private bill.

The total net cost of combating foot-and-mouth disease during the financial year ending March 31st, 1926, was £311,980.

Owing to the difficulties presented by the traffic problem in London, the Sunday processions making collections for hospitals, which have been made since 1920, will not in future be allowed.

Antimalarial measures undertaken in India by the provincial Governments include prohibition of the cultivation of rice near certain towns, the formation of quinine at low prices. The area under cinchona cultivation is being steadily increased with a view to making India self-supporting in the supply of quinine.

## Medical News.

WE have received a copy of the Labour party's *Report on the Nursing Profession*, which is to be submitted to a conference of nursing and kindred organizations at the Caxton Hall, Westminster, on January 28th. The report, which has been prepared by a subcommittee of the Standing Joint Committee of Industrial Women's Organizations and the Labour Party's Advisory Committee on Public Health, says it is undoubtedly the case that the nursing profession, consisting of those who have undergone a course of long technical training, is relatively worse off with regard to remuneration, hours, and general conditions of labour than any other similar group of workers. For probationers in hospital service, a forty-eight-hour week and an eight-hour day are recommended, together with a minimum salary of £40 a year, better living accommodation, an annual holiday of three weeks, no night duty during the first year's training, with not less than one full day a week and one week-end a month off duty. In regard to fully trained nurses in the hospital service, the report declares that the only way in which they can deal effectively with their conditions and exercise any sort of equality in bargaining power is for the profession to be organized on trade union lines. Until a national joint council, representative, on the one hand, of the nursing services, and on the other hand, of the State, municipal, and other employers concerned, can be inaugurated, certain minimum standards are laid down which the report states those responsible as employers should endeavour to see carried out. These include a forty-eight-hour week, not less than four weeks' annual holiday with full pay, rates of pay high enough to enable a nurse to live comfortably, to take a good holiday, and to contribute to a pension scheme which would give her the right to a pension at the age of 55 upon which she can live.

THE Central Midwives Board for England and Wales held a penal and an ordinary meeting on December 2nd. It was announced that the Ministry of Health had approved, subject to certain minor alterations and additions, the new rules for a period of one year from December 31st, 1926. A resolution recording the Board's appreciation of the valuable services rendered by the late Dr. W. E. Fothergill as an examiner at the Manchester-Liverpool centre was adopted.

THE managers of the Royal Institution have elected Mr. Julian Huxley, M.A., to be Fullerian Professor of Physiology. He has been Professor of Zoology at King's College, London, since 1925, and was formerly senior demonstrator in zoology at Oxford. He is the eldest grandson of Thomas Henry Huxley.

A NEW hospital for Dunbar is being prepared and will shortly be ready. The old Battery Hospital on the north side of Dunbar New Harbour has been closed, as it has suffered considerably from recent storms and is in a dangerous state.

DR. REGINALD S. PEARSON, Mayor of Lambeth, has called a meeting of medical men at his house, "The Hawthorns," 193, Clapham Road, S.W.9, to hear an address by Dr. Camac Wilkinson on tuberculin in the diagnosis and treatment of tuberculosis. The meeting will take place on Thursday, December 16th, at 4 p.m. All medical men interested are invited to attend.

THE last of the series of lectures arranged for this session by the Fellowship of Medicine and Post-Graduate Medical Association will be given by Mr. Ernest Clarke, on emergencies in ophthalmic practice, on Thursday, December 16th, at 5 o'clock, at 11, Chandos Street, Cavendish Square. This lecture is free to members of the medical profession. A further series of lectures on emergencies in medicine and surgery is being arranged for January, February, and March. There will also be a series of clinical demonstrations in ophthalmology and surgery, of which particulars will be announced later. Queen Charlotte's Hospital provides practical courses in obstetrics, lasting from two to four weeks; weekly courses in obstetrics and child welfare are undertaken by the staff of the City of London Maternity Hospital; and the Fellowship can arrange for clinical assistantships at the Samaritan Hospital. The following special courses will be held in January: a fortnight's intensive course in medicine, surgery, and the specialties at the Prince of Wales's General Hospital from January 10th to 22nd; a fortnight's all-day course in cardiology at the National Hospital for Diseases of the Heart, from January 17th to 29th (entries limited to twenty); a fortnight's course in diseases of children at the Royal Free Hospital and the Children's Clinic, from January 10th to 22nd; a month's course (Tuesdays and Saturdays at 11 a.m.) in psychological medicine at the Bethlehem Royal Hospital, from January 11th to February 5th.

Syllabuses of the special courses, the programme of the general course, and copies of the *Post-Graduate Medical Journal* can be obtained from the Secretary of the Fellowship.

THE Post-Graduate Hostel will hold three meetings next week at the Imperial Hotel, Russell Square, W.C.1, at 9 p.m. On Tuesday, December 14th, Professor C. A. Lovatt Evans, F.R.S., will discuss capillary circulation; on December 15th Mr. A. E. Mortimer Woolf will read a paper on pain; and on December 17th Dr. T. Wilson Parry will discuss the various holes discovered in the skulls of prehistoric man. Dinner at 8 o'clock (5s.). All medical practitioners are welcome.

A CHADWICK public lecture on legal conceptions of public health will be given by Mr. William A. Robson, B.Sc., Ph.D., Barrister-at-Law, in the Lecture Hall, Royal Sanitary Institute, 90, Buckingham Palace Road, on Monday, December 13th, at 8 p.m. Admission is free. Further information about Chadwick public lectures may be had from the secretary, Mrs. Aubrey Richardson, O.B.E., at the offices of the Trust, 13, Great George Street, Westminster.

AT an evening meeting of the Pharmaceutical Society of Great Britain, on Tuesday, December 14th, Mr. F. H. Carr, C.B.E., F.I.C., will open a discussion at 8 o'clock on the vitamins in their relation to pharmacy. The meeting will be held in the society's house, 17, Bloomsbury Square, W.C.1, and medical friends of members will be welcomed.

A CONGRESS of the Royal Institute of Public Health will be held in Ghent, from June 1st to 6th. The work will be divided into five sections—namely, State Medicine and Municipal Hygiene; Naval, Military, Air, and Tropical Diseases; Industrial Hygiene; Pathology, Bacteriology, and Biochemistry; and Women and the Public Health. The inclusive charge for first-class travelling, hotels, and excursions to Bruges, Brussels, and the Flanders battle-fields will be twelve guineas. It is stated that the Minister of Health is prepared to consider applications from sanitary authorities for sanction of the payment of the reasonable expenses of delegates, and that similar sanction has been obtained from the Scottish Office. Further information may be obtained from Dr. T. N. Kelyack, 37, Russell Square, W.C.1.

THE eighth Congress of the International Society of Surgery (to which Germans will be admissible) will be held at Warsaw, under the presidency of Professor Hartmann of Paris in July, 1929, when the following subjects will be discussed: (1) Causes and mechanism of post-operative embolism. (2) Results of resection of the stomach for gastric and duodenal ulcer. (3) Treatment of Graves's disease. Further information can be obtained from the general secretary, Dr. L. Mayer, 72, Rue de la Loi, Brussels.

THE thirty-sixth French Congress of Surgery will be held in 1927, under the presidency of M. Bégouin of Bordeaux. The subjects to be discussed include drainage in abdominal surgery, chronic pericollitis and epiploitis, and the results of periaarterial sympathectomy in affections of the limbs.

AN international post-graduate course will be held in Vienna from February 7th to 20th, and will deal with neurology and psychiatry from the therapeutic standpoint. Further information may be obtained from Dr. A. Kronfeld, 22, Porzellangasse, Vienna IX.

THE Fourth English-speaking Conference organized by the National League for Health, Maternity and Child Welfare was held from July 5th to 7th, and attracted an audience of nearly 1,000 people from twenty-four different countries. The verbatim report of the proceedings has now been published and may be obtained from the headquarters of the League at Carnegie House, Piccadilly, W.1, price 2s. 6d. Among the subjects dealt with are the prevention of rheumatic heart disease in young children, the care of children in the first five years of life, and publicity methods in maternity and child welfare.

THE address of the Board of Control (Lunacy and Mental Deficiency—England and Wales) is now Caxton House West, Tottil Street, Westminster, S.W.1. Telephone number: Victoria 8540. Telegraphic address: Aricenna, Sowest, London.

THE Council of the Harveian Society of London has selected the following subject for the Buckton Browne Prize: "The pathology, diagnosis, and treatment of new growths originating in the walls of the urinary bladder." The prize, consisting of a medal, together with the sum of £100, will be awarded for the best essay on this subject. It is open to any member of the medical profession registered in the British Isles or Dominions, and is limited to candidates under 45 years of age. Essays must be sent in by November 1st, 1927. Further particulars may be obtained from the honorary treasurer, Dr. G. de Bec Turtle, 81, Cambridge Terrace, Hyde Park, W.2.

ON his retirement from the position of school medical officer at Hull Dr. James Fraser has been presented by the education authority with a framed resolution of appreciation of his service, engrossed on vellum.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.** ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication. Authors desiring REPRINTS of their articles published in the British Medical Journal must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. All communications with reference to ADVERTISEMENTS, as well as orders for copies of the Journal, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the British Medical Journal are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines). The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the British Medical Journal, *Antiology Westcott, London.*  
**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Antiology Westcott, London.*  
**MEDICAL SECRETARY**, *Mediscra Westcott, London.*  
 The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Mediscra, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

"W. J. K." asks for advice in the treatment of a long-standing, progressive, and pronounced case of obesity.

## TREATMENT OF TINNIUS.

"Dr. P." would like to know whether success has ever followed puncture of the tympanum in cases of very troublesome tinnitus. Every other treatment has been tried without avail. The patient is 56 years of age.

## NERVOUS RITCHING.

"S. P. S." writes to suggest that "H. T.'s" patient should try sucking small pellets of camphor.  
 "M.B., B.Ch., B.Dent.Sc." writes in reply to "H. T.": May I suggest (1) that the filing away of the back of an upper denture and the production of a fine thin edge are often sufficient, but by the patient with the back of a small teaspoon, after sucking a "Rhodia" pastille containing mentholform (made by L. Durand, 21, rue Jean Gonjon, Paris 8<sup>e</sup>), and (3) the application of a little oil of cloves to the palatal surface of the denture will, in a short time, overcome the nervous itching.

## LICE ON DOGS.

Dr. J. AUBREY IRELAND (Shrewsbury) writes with reference to the reply given on December 4th (p. 1087): As one who has bred show and working dogs for the last thirty years I have from time to time had trouble with lice, and, after trying many methods, I am convinced that much the best way is to use oil of sassafras (synthetic). A little (a drachm or two for a 20 lb. terrier) shaken over the dog from a sprinkler-top bottle and well rubbed in, particularly attention being paid to the neck and around the ears, will disinfest the dog in a couple of days; he should then be washed. Care must be taken that he is kept in an airy place, as if shut up in a close box he is liable to be overcome by the fumes. I have not found it necessary to repeat the dressing, but of course the bedding, etc., should be cleansed or renewed.

## TREATMENT OF PRURITUS ANI.

Dr. ALFRED A. MASSER (Penistone) writes: I note with satisfaction the importance attributed to the cleansing of the hands following defaecation. As your readers probably know, it is part of the ritual of the Jewish race to wash the hands after defaecation with the uttering of a prayer. I feel confident that the rarity of parasitic intestinal worms in this race is to great extent attributable to this ancient rite, which is closely observed by most Jews. Water is also poured over the hands prior to partaking of any food, which traditional law might be put into practice with great benefit by other races. In my own experience of the treatment of pruritus ani, where no general or local cause can be found, the application of pure liquor picis carbonis on three successive nights, together with frequent cold douching of the anal region, has given great relief, and in many cases resulted in rapid cure.

## INCOME TAX.

*Sale of Practice.*  
 "Nestor" is likely to sell his practice as from September, 1927. How should his liability for 1927-28 be calculated, and should he pay certain expenses this year and so ensure that they affect the liability for that year? Past assessments have been on the "cash" basis, as regards both receipts and expenses.  
 Assuming that the change from the three years' average to that of the previous year takes effect for 1927-28, "Nestor"

In connexion with the scheme drawn up by a committee of the International Society of Medical Hydrology for teaching this subject at the universities and medical schools, nearly sixty medical graduates and students of Bristol University recently visited Bath. A lecture demonstration was given at the Royal Mineral Water Hospital by Dr. Vincent Coates, dealing especially with rheumatic affections of muscular and fibrous tissue, infective arthritis, metabolic arthritis, and osteo-arthritis, cases being shown to demonstrate each type. This was followed by a visit to the Royal Baths, where demonstrations of hydrotherapy were given, and to the accessory department of the bathing establishment, which included ultraviolet rays, radiant heat, Bergonié treatment, diathermy, etc. A description of the new radiological department at the Royal Infirmary, Edinburgh, appeared recently in the *Electrical Review*, and has now been reprinted in pamphlet form by Watson and Sons (Electro-Medical), Ltd., who were responsible for the supply and installation of the x-ray and electro medical apparatus. The reprint is fully illustrated and gives a good idea of the excellence of the department, the opening of which by the Duke of York was reported in our issue of October 16th (p. 710).

The late Mr. Oscar Wilkinson by his will bequeathed £1,000 each to the Scarborough Hospital and Dispensary, the Scarborough Cottage Hospital, the Scarborough Convalescent Home for Children, the Hull Royal Infirmary, the Sheffield Royal Infirmary, the Cancer Hospital, Brompton, St. John's Hospital for Diseases of the Skin, Leicester Square, W.C., and St. Dunstan's Hostel for the Blind.

The eighth edition of Treves's *Surgical Applied Anatomy*, revised and enlarged by Professor C. C. Choyce, will shortly be published by Cassell and Co., Ltd. It includes a number of new illustrations.

In the October number of the *Quarterly Review of Biology* there is an illustrated article on the foetal growth of man and other primates, by Adolph H. Schultz, of the department of anatomy of the Johns Hopkins University. He finds that human racial differences, and all distinctions between man and apes or monkeys, increase during some periods of embryonic growth, and never become less with advancing development. This is held to support the current theory of one common ancestry for all the primates. The journal may be obtained from Messrs. Baillière, Tindall and Cox, Henrietta Street, Covent Garden.

The annual report of Livingstone College for 1925 to 1926 quotes warm appreciations of the work of the college by missionaries in Labrador, Kenya, Slam, and North China. In addition to the full session of nine months' medical training for missionaries from October to June, a vacation course is held in July, and intensive three-day courses of lectures in the care of health in the tropics are given in March, September, and December. Further information may be obtained from the Principal, Livingstone College, Leyton, E.10.

The late Mr. Thomas Martin of Pollokshields has by his will bequeathed £2,000 to the Royal Hospital for Sick Children, Glasgow, to endow a "Margaret Inglis Sim" cot; £1,000 to the Glasgow Royal Cancer Hospital, to be used especially for research work; £1,000 to Biggart Hospital Home, Prestwick, to endow and name the "Margaret Inglis Sim" cot; and £1,000, or such sum as may be required, to the West High and Cottage Hospital, to endow the "Margaret Inglis Sim" bed. The residue of the estate, subject to other legacies and certain annuities, is left in equal shares to the East Park Homes, Glasgow, the Maternity Hospital, Glasgow, and the Samaritan Hospital, Glasgow.

The sanitary condition of Moscow, according to a statement in the *Münchener medizinische Wochenschrift*, is in many respects better to-day than in 1913. Several epidemic diseases are less prevalent than before the war, as is shown by the following figures: typhus, 320 cases in 1913, 240 in 1925; relapsing fever, 64 cases in 1913, 50 in 1925; dysentery, 800 cases in 1913, 320 in 1925; diphtheria, 4,600 cases in 1913, 2,000 in 1925; small-pox, 217 cases in 1913, 10 in 1925. Enteric fever is an exception to the rule, owing to the bad water supply and consumption of raw milk, there being 2,500 cases in 1925 as compared with only 1,000 in 1913.

On the occasion of the thirtieth anniversary of the foundation of the Dutch Dermatological Association, on October 24th, Drs. J. J. Jadassohn of Breslau, E. Finger of Vienna, Darier of Paris, C. Rasch of Copenhagen, P. G. Unna of Hamburg, Levaditi of Paris, G. Peinert of London, B. Bloch of Zürich, and J. Almkvist of Stockholm were elected honorary members.

At Exeter police court, on December 2nd, a man was sentenced to two months' imprisonment for the theft of a stethoscope, colloidum, and soda tablets from a chemist. He is stated to have obtained these by pretending to be a qualified medical practitioner.

should see that any expenses which would ordinarily be paid in 1926 are not postponed to 1927, but it would perhaps be unwise to anticipate payments which would normally fall into 1927. If the inspector of taxes has reason to suppose that owing to any departure from the usual procedure the cash basis has ceased to reflect the full earnings of the practice, he would be quite justified in refusing to accept that basis. For 1927-28 "Nestor" will be liable in respect of one-half of the assessable profits; the balance of the assessment will have to be dealt with by his successor.

#### Motor Car Transactions.

"J. H. P.'s" transactions have been as follows: In August, 1925, he bought a motor cycle for £45, and in May, 1926, sold it for £25 and bought a motor car for £149. In August, 1926, he sold the motor car for £135 and bought another for £235. The changes were effected because the original cycle and car were unsuitable.

"In his assessment for 1926-27 "J. H. P." is entitled to depreciation on the vehicle held at the end of 1925-26 plus (as an expense of the year 1925-26) the cost of replacing the cycle. The inspector is, perhaps, a little lenient in making the second deduction, as the exchange does not seem to have been due to obsolescence. On the whole the total allowance made seems reasonable, but it should, of course, be greater next year owing to the use of the more expensive car.

"A. B. C." bought a car in 1923 for £265 and replaced it in 1925 with a bigger, better car costing £360. The inspector of taxes refuses the "obsolescence" allowance on the ground that the car was not obsolete.

"If, as may very well have been the case, the 1923 car had become unsuitable for the work required of it, we consider that "A. B. C." was fairly entitled to regard it as obsolete for his purposes and to claim the obsolescence allowance. If that ground of claim fails, "A. B. C." might consider whether it would not be better for him to give up his claim to the percentage allowance on the new car, and continue now and in the future to deal with the question by claiming the costs of renewal as and when incurred. We assume that he did not receive a depreciation allowance for 1925-26.

#### LETTERS, NOTES, ETC.

##### OSTEO-ARTHRITIS OF THE HIP-JOINT.

DR. W. J. MIDDLETON (rse of a note on Dr. Warren Crowe' (November 6th, p. 834), emphasizes the non-specific toxin was used over a long period. Dr. Middleton maintains that there is no difference etiologically between osteo-arthritis and rheumatoid arthritis, and attributes the pain in the former case to muscular spasm. By crossing the foot of the affected limb over the tibia of the other leg great pain is elicited, and this he regards as diagnostic. He has successfully treated a case of osteo-arthritis by multiple acupuncture and irritants, and another by galvanocautery of the back, close to the spinal column. He refers to Petersen's theory that the effects of the cautery, blister, and seton come under the heading of non-specific protein therapy.

##### TREATMENT OF CARBUNCLE.

SIR JOHN O'CONNOR (Buenos Aires) invites surgeons who, irrespective of coincidental diabetes, treat carbuncle by excision, crucial incisions, or fuigation, to give the following physiological method a trial and note the result at the end of fourteen days. Except when the patient is asleep, apply fomentations of a hot corrosive sublimate (1 in 3,000) every hour, avoiding employment of any impermeable tissue in the superimposed dressing, which should consist merely of a good pad of absorbent wool and a bandage. In combination with this local treatment the patient should be fed up, not omitting his co-efficient of alcohol.

##### MAD DOGS.

SOME of the more excitable portions of the lay press have recently given considerable prominence to accounts of what they call viciousness or treacherousness among some of the larger breeds of dogs, and it may be of interest to explain what really is happening.

Shortly after the war a breed of dog was introduced into this country from the Continent and it immediately became popular under the very misleading name of the Alsatian wolfhound—misleading because it was not an inhabitant of Alsace, has no connexion whatever with a wolf, and is not a "hound." This breed of dog has been known for centuries on the Continent as the German or Continental sheep dog or shepherd dog—titles which adequately describe the dog and its function. It is very closely related to our own collie, and in pure bred litters of "Alsatians" pups are sometimes met with which are almost indistinguishable from a short-haired collie. Like the collie, it is a highly strung and extremely nervous. The sudden access of war caused very intensive breeding with it came all the evils of inbreeding by the continued importation of fresh blood from

abroad, but in some cases this was not done, and this is, in part at least, responsible for the recent scare. In a few cases dogs, otherwise affectionate, suddenly became mad—became, indeed, the canine equivalent of a homicidal maniac—and savaged their owners. This is liable to happen in all breeds of dogs—and, indeed, several of the recent cases were in other breeds—but the popular belief, fostered by the name, that the Alsatian was crossed with a wolf, has caused the discredit of all of these cases to be given to this breed. The treachery of a half-bred wolf differs much from the cases under notice. Though such an animal may be obedient to its master, it never has the affection of the dog (and the "Alsatian" is "all dog"), and its behaviour is such as to make one expect treachery if given a suitable opportunity. It is unfortunate that a pure dog should have been so unsuitably labelled; it is the more unfortunate because the wolf-like characters are really dog characters which have been less distorted by the breeder than in most of the other animals which have come under their charge.

It is important, too, for laymen in general to understand that rabies does not now exist in this country, and that, under the very stringent conditions of quarantine imposed by the Ministry of Agriculture on all canine animals entering Britain, it is unlikely ever to gain a foothold here. The layman does not understand this, nor does he understand that a bite from a dog (even from a mad dog) which is not rabid will have little more result than a bite from any other animal. It may cause a local abscess or even more general symptoms, but it can never cause hydrophobia. The medical profession could do a considerable public service and allay much public apprehension by giving prominence to these facts.

##### AN ANCIENT NEEDLE.

DR. SEYMOUR W. DAVIES (Wallasey) writes: The note by Dr. G. Varian in the BRITISH MEDICAL JOURNAL (September 18th, p. 518) entitled "An Ancient Needle" reminds me of a case I saw about three years ago. A man, about 55, who has tabes dorsalis in a mild form, which does not prevent him from following his occupation of accountant, complained of a sudden pain in his left thigh, about Scarpa's triangle. The pain was followed by ecchymosis and a tender hard nodule in the skin. I ordered lead and opium lotion and Donovan's solution, thinking that he had phlebitis or thrombosis. Ten days later the swelling fluctuated and I aspirated 2 drachms of altered blood. A week later I felt a foreign body under the skin, injected novocain and extracted a darning needle 4 in. long and clean, though discoloured. The only explanation was that the needle had slipped from his desk into his "lap," and had been driven inwards by flexion of the thigh. His tabetic state would presumably account for his not noticing pain, though his sensibility to the pain of the events described above was normal enough. I may say that he is a sober man and the case has remained a puzzle to me.

##### MEDICINE IN FICTION.

IN the current number of the *Newcastle Medical Journal* Dr. Hugh Dickie, following in the footsteps of Sir Squire Sprigge, sets forth something of the "Nosology of the novelist," illustrated by excerpts from works by modern authors. Thus from *The Great Babylon Hotel* of Mr. Arnold Bennett he calls what is probably the most complete account ever written of the symptoms of that mysterious disease "brain fever": The patient, Prince Eugen, had a flushed face and unequal pupils. He muttered and whined. When he got up he staggered and fell in a swoon. At this point his eyes closed, and he breathed through his nostrils. His fingers contracted, and from time to time general convulsions occurred. It is satisfactory to learn that prognosis in these cases is good, and that perfect recovery in body and mind is possible. After such a formidable disease the description by Hugh Conway of a patient operated on for double cataract at one sitting, with immediate restoration of sight and without the need for glasses, seems comparatively tame. Sir A. Quiller-Couch has a doctor who fortunately carries a bottle of bromide in his pocket, and when called to treat a madman who has just committed a murder, produces sleep and sanity with a dose of this potent drug. "Sapper," on the other hand, shocks the shade of Harvey by making the arteries convey to the heart a dreadful poison which has been placed upon the skin. Dr. Dickie suggests that the literary giant should consult his family doctor before committing these medical concepts to paper.

##### AN OPHTHALMOLOGICAL CURIOSITY.

A CORRESPONDENT sends us an extract from one of the Scottish newspapers describing the impressions produced upon an American journalist by an audience with Signor Mussolini. Il Duce, according to this keen observer, "has a very winsome smile, looks at you with distinct directness, has brilliant black eyes, with a trick of enlarging them, showing wide rings of white cornea around the retina." This annular corneo-retinal phenomenon has not, we believe, been described hitherto in any detail.

##### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 251.

British Medical Association.

MEETING, NOTTINGHAM, 1926.

SECTION OF LARYNGOLOGY AND  
OTOLOGY.

A. BROWN KELLY, M.D., D.Sc., President.

DISCUSSION ON  
THE AFTER-TREATMENT AND RESULTS OF THE  
SIMPLE AND RADICAL MASTOID  
OPERATIONS.

OPENING PAPERS.

I.—GEORGE J. JENKINS, F.R.C.S.,  
Aural Surgeon, King's College Hospital.

THE SCHWARTZ OPERATION FOR ACUTE MASTOIDITIS:  
AFTER-MANAGEMENT OF THE WOUND.

The selection of a title for this paper presents some difficulty, as for the moment we are concerned, not with the actual operation, but only with the after-treatment of the wound. No doubt some of us may contend that this depends on the details of the operative procedure, but I think that for the basis of the discussion we must assume that the operation has been done with meticulous care, and that all diseased tissues have been removed.

Whatever method of treatment is adopted, the primary object should be the prevention of an extension of the septic process. It is, however, important to consider how the ear may be left as near normal as possible, and how both these objects may be attained with the least loss of time. Let us in the first place have a clear understanding as to the purpose of the operation. It is a general rule in surgery that a pyogenic abscess or a septic region should be drained as freely as possible, as it has been found that unless the whole of the affected part can be removed, efficient drainage is the best preventive in our power against extension of the inflammation. As to how long the drainage should be maintained, this seems to depend upon the relation of the degree of resistance of the patient, to the virulence of the infection, and also upon the time required for permanently damaged tissue to be absorbed or thrown off. Thus we find a single tapping of an abscess may be sufficient to promote recovery, whereas in other cases efficient drainage may have to be maintained over a long period.

It seems to me that what we have chiefly to consider is the application of this principle to the treatment of the operation wound in acute mastoiditis. In this condition the region infected includes, in a majority of cases, the nasopharynx, Eustachian tube, tympanic cavity, mastoid antrum, and possibly an extensive system of cells in the mastoid. When the middle-ear tract has been infected we dread the dangers of an extension of the infection beyond the mucous membrane, and for this reason we establish drainage. By the Schwartz operation we remove, as far as possible, the damaged tissues behind the aditus, but at the same time we should make quite sure that the tympanic cavity is sufficiently drained either by spontaneous opening or by paracentesis. It is also important to deal with all systems of cells in the mastoid, including those which may not appear obviously infected. The position then will be that behind the aditus the whole of the diseased tissue will have been removed, and there will be sufficient drainage of the tympanic cavity. The walls of the mastoid wound, no matter how carefully cleaned, or what antiseptics are used, must be regarded as infected with an organism which has been responsible for the acute mastoiditis and is capable of causing still further extension of disease, in spite of the resistance of the individual. The object of this paper is to direct your attention to the after-management of this septic wound.

*Primary Suture.*  
It is well known that many septic wounds after careful cleaning, and with or without the use of antiseptics such as iodoform or bipp, can be closed and primary healing occurs, though even when the greatest care is taken this procedure sometimes fails. The same principle is seen in the occasional recovery after a simple puncture of an abscess. We know also that the tissues are capable of dealing with a certain dose of organisms, this dose varying with the resistance to the organism in question. It is obvious, therefore, that if by some misfortune a massive dose is left in any part of the wound, or a smaller dose in a favourable situation, such as a blood clot, then a reinfection will occur and the wound will break down. In many parts of the body this may not be serious, or of sufficient moment to outweigh the advantages of primary union of the wound. In the particular region with which we are dealing such a recurrence of active inflammation may be a matter for grave concern. Since war experiences have been tried primary closure after the Schwartz operation. When considering the question of primary closure I came to the conclusion that there were certain extensive irregular cavities where the soft tissue could not be brought into intimate contact with the deep bony parts, and that in such circumstances primary suture was not likely to succeed and was unsafe. The only cases in which I have attempted this method of treatment have been those in which the cavity was of such a form that after cutting the bone edges away the soft tissues fell in contact with the bone, leaving only a comparatively small cavity near the mental wall.

Two other considerations have influenced my procedure in this connexion: first, the general condition of the patient clinically, and secondly, the appearance and character of the purulent exudate. In cases where this was thin and watery-looking, suggesting an inadequate local resistance, I have not attempted primary suture. It is impossible, even with the aid of sterile iodoform or bipp, to be certain that the wound is sufficiently clean, or that reinfection from the middle ear will be prevented. Even in my selected cases primary suture without drainage has occasionally failed, and I have felt that the risk and disturbance to the patient was too great, and the result, even when successful, not always satisfactory. In some of the instances in which primary suture was successful the organization of the clot under the skin was evidently feeble, and the result in some cases was a large cavity thinly covered by skin, while in others there was very marked depression.

*After-Treatment by Maintenance of an Open Wound.*  
This has been practised by using the whole or part of the mastoid incision, or by making another drainage wound into the meatus and closing the original wound. I propose to deal first with the latter of these two methods. It seems to me that an opening into the meatus cannot afford efficient drainage for a great many of the cavities following a Schwartz operation, since such an opening can only provide drainage for the immediate neighbourhood, such as the antrum and the antero-superior part of the mastoid cavity. From this it would appear that the only suitable cases for this method of treatment are those in which the wound cavity is small, and in these I cannot see any advantage in favour of meatal drainage over drainage from the lower part of the mastoid incision after closure of the upper part. In fact my experience teaches me that, even in selected cases, drainage from the lower part of the mastoid wound is more effective, and the healing is as rapid and is less painful. I cannot help saying that I feel that the advocates of meatal drainage allow themselves to be biased too much by the pleasant appearance of a healed posterior incision, and are not sufficiently influenced by the sometimes unpleasant effects of meatal drainage. At times treatment of the meatal wound is difficult and painful—at least it has been in some of my own cases, in which granulations had to be treated and meatal dermatitis overcome. Occasionally, even when healing was satisfactory, the depression in the meatus caused trouble for some time afterwards. In short,

I cannot myself see any advantage in meatal drainage. I have boldly made this statement because I feel it is a point on which there will be difference of opinion, and on which there should be discussion. I know it is the practice of not a few men for whom I have the greatest respect to use meatal drainage, and I would ask them to give clear and definite reasons for their preference for this method over the other.

We have now to consider a variety of treatments of the wound by drainage through the mastoid incision. The problem will vary with the conditions. At one extreme there will be a small smooth-walled cavity, of the dense mastoid, and at the other will be the large irregular cavity with tracks in various directions, and rough irregular bony walls. Sometimes the cavity is necessarily deep even at the edges, and at other times it is shallow. No two cavities are alike, and the appropriate treatment for each type must be considered. I do not think hard and fast rules can be drawn up for the adoption of any particular method; the operator must be influenced by the conditions present, and, apart from the extreme variations mentioned, there must be a difference of opinion in certain cases. The form of the cavity is not the only factor, as I am sure most of us would take into account the acuteness of the infection and the character of the pus, and also the general condition of the patient.

I now propose briefly to describe my ordinary practice. I syringe out all wounds, first with hydrogen peroxide (10 vols.) to remove finer particles of bone or tissue which may have escaped notice, and subsequently with some bland sterile lotion; all the walls are then lightly smeared over with sterile fine iodoform prepared as follows: iodoform in fine powder is soaked in absolute alcohol; the excess of alcohol is run off and the iodoform used as a paste. When there is a small well defined cavity, such as a simple gutter in the anterior part of the mastoid, it is my custom to stitch up the upper part of the incision, and to drain from the lower part of the wound. Two-inch ribbon gauze impregnated with iodoform is loosely packed in the part of the cavity below the antrum; there is a certain amount of room for the blood clot to form in contact with the walls of the cavity. The gauze is there merely to maintain an exit for septic exudate. At the subsequent dressing, about the third day, a similar gauze dressing, perhaps a little smaller, is placed in the wound, and fresh clot usually forms which sometimes organizes very quickly. It is often advisable, even for such a light dressing as this, to administer gas. Two or three rubber tubes in the place of the ribbon gauze make an equally satisfactory drainage system. The process of healing is commonly uneventful, and the resulting scar is not in any way objectionable.

When the wound is very large it is my custom in most cases to leave the whole of the incision open and to pack lightly all parts of the wound with iodoform gauze. Such a large packing necessitates gas anaesthesia for the first dressing on the third or fourth day. The wound is practically always healthy by this time, and the repacking is done much more lightly and less extensively. This method of treatment has not given me any cause for anxiety or regret, whereas simple drainage of the cavity from the lower part of the incision by means of tube or gauze has often resulted in general toxic effects. In some of the extensive cases, where the cavity is very shallow and other conditions are suitable, I allow the soft tissues to come into contact with the bony wall, but I always pack the lower and anterior part of the cavity. I am quite well aware that many of the cases treated as indicated above would heal by primary union, provided the middle-ear condition was satisfactory, but it is the odd case with serious disturbances resulting from reinfection that drives me to a method that has been proved safe and satisfactory, though it may mean a prolonged after-treatment.

If there is any serious delay in healing, or if there is a tendency for the epithelium to dip into the wound, I strongly advocate secondary suture, which very rarely fails if carefully performed. For this procedure I like to see the communication with the middle ear shut off, or almost completely closed; by this time a considerable part

of the wound has been filled with granulations and the cavity is practically aseptic. My method is as follows. The cavity is thoroughly cleaned out with 2 per cent. solution of iodine. The edges of the wound are cut away back to healthy skin, the skin is undercut very widely and the flaps are made as thick as possible. The whole surface of the cavity is lightly smeared with iodoform, and the edges are brought together accurately without tension. The patient is able to go about in three or four days, and the wound is usually soundly healed in ten to fourteen days. Secondary suture gives the soundest scar and the best cosmetic result of any of the methods of treatment that I have tried, and also shortens the period of convalescence considerably.

I have not referred to the persistence of sinus or fistula, as in my opinion this condition is due to an imperfect operation, or imperfect treatment of the infection in the more anterior part of the middle-ear tract. Considerable delay in the healing of the Schwartz wound may be caused by a septic nasopharynx, and for this reason I often remove the tonsils and adenoids when for any reason a second anaesthetic becomes advisable. The main object of this paper is to direct your attention to certain differences of practice in the after-treatment of the Schwartz wound. You will discuss primary suture. Some of us contend that when primary suture fails there is a certain amount of gain. I personally feel that the disturbance and risk to the patient from the occasional secondary infection is too big a price to pay, and also I do not think the ultimate result satisfactory, even when there is primary healing. Again, you will consider meatal drainage—a method used by a number of men who have had large experience. I do not practise meatal drainage for the reasons given above. You will criticize the various methods of treatment of the cavity through the original mastoid incision, and also secondary suture.

In this discussion we shall be inclined to support those procedures that promise for the patient an easy convalescence and a rapid return to normal, but we should disapprove of any procedure that promises these benefits if it involves the least risk of sacrificing a small degree of safety.

II.—J. S. FRASER, M.B., Ch.B.Ed., F.R.C.S.Ed.,

Surgeon to the Ear and Throat Department, Royal Infirmary, Edinburgh.

BEFORE considering the after-treatment and results of the radical and modified radical mastoid operations we must ask ourselves what objects we hope to attain by these procedures. The first and most important is to place the patient in a position of safety as regards life—that is, to free him or her from the possibility of an intracranial complication, or, as the modern slogan has it, "safety first." The subsidiary objects are to stop the aural discharge, and to improve, or at least retain, the hearing in the affected ear. In twenty years Dr. Logan Turner and I have known of only one case in which an intracranial complication occurred in a patient who had had a radical mastoid operation, but we have known of several in which a patient suffering from chronic middle-ear suppuration, without any acute symptoms, came for examination, had his name entered on the waiting list, and had to be taken in as an urgent case of intracranial complication before his turn came for admission.

#### INDICATIONS.

The indications for the operative procedures under consideration do not come officially within the scope of this paper. I do not intend to say anything about the indications for the radical mastoid operation except that we must all admit that now and then we operate on a case in which we find at operation little or no sign of serious disease in the antrum, aditus, or attic. Many of these cases, attending as out-patients, ought to be cured by conservative treatment, including ionic medication. The difficulty is to get efficient conservative treatment in the cases of patients who live in the country. If we had sufficient hospital accommodation to admit these patients for two or three weeks it is probable that many of them would not come to the radical operation.

With regard to the modified radical operation, my practice has been to limit this operation to cases of chronic

middle-ear suppuration with good hearing in the affected ear, or to cases in which the "other ear" is very deaf, or at least more deaf than the ear to be operated upon. In many of these cases the perforation is in the attic region, or is a posterior marginal one; both are very frequently associated with cholesteatoma, so that a slight risk is incurred by omission to perform the complete operation. This risk is, however, justifiable.

Brühl does not favour the modified operation, and says that, since using the Bárány noise box to exclude the sound ear, he no longer finds "good hearing" in the ear to be operated upon. Further, he finds that patients in whom the "conservative" operation has been performed by others hear just as badly as his own "radical" cases.

I do not perform the modified radical operation in cases of acute middle-ear suppuration, as recommended by Mr. Heath, because I hold that the Schwartz or simple mastoid operation is more suitable. In most of these acute cases the diseased cells extend down to the tip of the mastoid, which lies at a lower level than that of the meatal floor.

#### TECHNIQUE.

Without a word or two about the technique of the operations under discussion, it is almost impossible to deal with the after-treatment and results, which depend to a very large extent on the operative methods employed. I will not enlarge on the necessity of removing the whole of the lateral wall of the antrum, aditus, and attic, of curetting very thoroughly the Eustachian tube, of lowering the bony floor of the meatus and the facial spur to the limits of safety, of removing the remains of the drumhead, including its tendinous attachment to the annulus, of removing polypi and granulations and curetting diseased areas on the inner wall of the bony cavity with due regard to the danger areas—the window regions. Two points, however, deserve detailed attention—namely, the meatal plastic and the immediate skin graft by Marriage's method.

**Meatal Plastic.**—Recently Bárány has omitted the meatal plastic, packing the mastoid cavity and leaving the post-auricular wound open for a period. Dan McKenzie and probably others have used a similar technique in this country. The object is to get rid of the tendency for collections of wax and cast off epidermis to form in the operation cavity. I have no personal experience of this method, but Dr. W. T. Gardiner tried it in one case, without success. Brühl does not favour Bárány's innovation. The objections to the method are that either the posterior wound would have to be left open and packed for a very long time or, if it were allowed to close, there would be a danger of the collection of pus under tension in the antrum. Brühl holds that Bárány's method will result in recurrences and further operation. My own preference is for the Körner plastic and a very large meatus; indeed, I usually excise a considerable piece of cartilage and stitch back the flap with a mattress suture. A large meatus not only facilitates inspection and after-treatment, but also tends to give a dry cavity. We have had very little trouble with perichondritis of the auricle. Brühl, after using the Panso and Stacke flaps for many years, has adopted, or readopted, Körner's method.

**Skin Graft.**—With regard to the primary skin graft I can confirm Mr. Marriage's claim that the operation cavity heals much more quickly, that the outline of the inner wall is preserved in almost all cases, that the first dressing is nearly painless and subsequent dressings are unnecessary, that the duration of the patient's stay in hospital is greatly reduced, that a dry and satisfactory cavity results in a larger percentage of cases than with other methods, and, finally, that the results as regards the hearing power are better than when the skin graft is omitted.

**Modified Radical Mastoid Operation.**—This procedure has several variations. After opening the antrum, we may remove only a small part of the posterior wall of the bony meatus; secondly, we may remove almost the whole of this wall, including part of the lateral wall of the aditus, exposing the short process of the incus and lateral canal prominence; thirdly, we may remove the incus (Sidney

Scott); fourthly, we may take away the outer wall of the aditus and attic, exposing the body of the incus and head of the malleus; finally, we may or may not skin-graft the cavity. The choice of operation depends on the type of case with which we have to deal—for example, in cases with attic perforation and cholesteatoma it is advisable to do a "liberal-conservative" operation and to remove the outer wall of the aditus and attic, whereas in cases without attic perforation and cholesteatoma, a "tory conservative" operation may be all that is called for. In any case we must admit that the modified operation is rather less likely than the radical to yield a dry ear. I usually explain to the patient that the modified operation is to be performed to safeguard his hearing, and that it may be necessary to complete the radical operation at a later date. Brühl is against the modified operation, and believes that those who are now trying it will in a few years return to the radical. Only one out of eleven cases operated upon in his clinic according to Bárány's method was a success.

#### AFTER-TREATMENT.

In the great majority of cases which have been skin-grafted there is very little to be said about the after-treatment. I apply the graft to the bony surface at the time of operation, by means of a long string of iodoform worsted which is packed into the cavity. Other surgeons use different methods (Mosher). The case is dressed on the fourth or fifth day, the silkworm-gut skin stitches, including that retaining the meatal flap, are taken out, and the iodoform worsted packing is removed. As a rule there is no bleeding and no necessity to clean out the cavity. In most cases I put in fresh iodoform worsted packing and apply gauze wool, and a trefoil bandage for another two days. At the end of this period all dressings are omitted in the daytime and the meatus is left open. At night a piece of iodoform gauze is inserted into the meatus, and cotton-wool and a bandage are applied so as to avoid staining the pillow. The case is now treated morning and night as one of chronic middle-ear suppuration, by means of peroxide drops, syringing with lukewarm boric lotion or dilute lysol solution (half a teaspoonful to the pint), drying out with gauze strips and the instillation of spirit drops containing 10 grains of boric acid in each ounce. The superficial layers of the graft come away of their own accord and should not be forcibly removed. The patient is, as a rule, able to leave the ward in fourteen days, either for the convalescent house or for his own home. Cases are usually seen at the end of three weeks after leaving hospital. Almost the only trouble I have known in these skin-grafted cases is the formation of a small abscess at the lower end of the retro-auricular wound about a week or ten days after operation, the upper part of the wound remaining soundly healed. We must remember that the patient is lying in bed and that any discharge in the operation cavity gravitates to the lowest part. Further, if after cutting the Körner flap the vessel in the lower cut edge of the cartilaginous meatus requires a ligature, the catgut may form the starting-point of such an abscess. As a rule, however, the retro-auricular wound gives no trouble. This may be due to the fact that in Edinburgh we make the incision in the hair margin so that the wound is united over periosteum and bone and not over the operation cavity itself.

In cases in which a skin graft is not applied the after-treatment is more troublesome on account of the formation of excessive granulations which grow up from the facial spur and downwards from the cut edge of the attic and aditus and tend to form about the level of the isthmus a membrane which shuts off the deeper part of the cavity. Frequently this membrane has a small hole in it through which pus exudes. In several of these cases I have operated again, and on the second occasion have employed the skin graft with success.

Such applications as scarlet red in rectified spirit and brilliant green do seem to promote the early epithelialization of the operation cavity, though sometimes they cause irritation of the skin. Sometimes there is a tendency of the auricle to droop to a lower level than that on the normal side or to stand out further from the head. I do

not know if this slight deformity can be avoided by using mental plastic methods other than Körner's as I have never tried them.

#### After-Care of the Operated Ear.

Even after the patient has apparently made a satisfactory recovery and the cavity has been completely lined with epithelium, some attention is necessary if things are to remain satisfactory. Unless the operation cavity is cleaned out at regular intervals wax and epithelium accumulate, so that in time the cavity is lined with a layer of debris beneath which there is some pus. Printed instructions are now given to all "radical mastoid" patients on leaving hospital. Further, they buy, or if too poor they are provided with, an efficient metal ear syringe. In very many cases, however, we find that the instructions have not been followed and the syringe has not been used. As a rule patients confess, when they report for inspection, that nothing has been done to their ears since shortly after they left the infirmary. In some the auricle and mastoid region have not even been washed with soap and water. This question of "after-care" is a very weak spot in regard to the operation. I often envy the abdominal surgeon who, at the end of the operation, closes up the wound; the patient gets better or dies, but, if he recovers, all he has to do is to wash the scar in his daily bath, if he is cleanly, or not to wash it if he is not. There is no operation cavity and no wax.

#### Causes of Failure to Obtain a Good Result.

Apart from inefficient operation we may enumerate:

(1) Failure to close the Eustachian tube and to get rid of the tubal air cells. Many of these cases occur in children; they are really cases of tubo-tympanic catarrh or suppuration, and are not suited for the radical mastoid operation. In such cases we should treat the nose and nasopharynx, try vaccine therapy, syringe out the tube either through the Eustachian catheter or from the external meatus by means of a bulbous-ended syringe, followed by inflation and injection of silver nitrate, argyrol, or collargol. I have no experience of artificial closure of the tube by means of bone splinters, or skin flaps and catgut. I always tell patients and their doctors that I cannot promise a perfectly dry ear after the radical mastoid operation, but since the introduction of Marriage's skin-grafting method our results as regards closure of the tube have been much better. In cases in which the radical operation has been performed Brühl, who does not believe in closing the tube, recommends drying out the cavity with hot air, probably by means of a dental appliance. He also mentions the application of trichloracetic or lactic acid to the tubal region and exposure to real and artificial sunlight.

(2) A faulty state of the patient's general health. During the war, when we were operating on young and otherwise healthy men, it was remarkable how well the radical mastoid cavity healed—much more quickly than in ordinary hospital cases.

(3) Narrowness of the external meatus and want of care of the operation cavity have already been dealt with.

#### PROGRESS.

With the object of obtaining statistics as accurate as possible I requested all patients operated on in the years 1919 to 1925, inclusive, to report at the infirmary for re-examination. At first I tried to do this work myself, but found that it took up so much time on waiting days that I could not get through the ordinary work in a proper way. I therefore asked my clinical tutor, Dr. J. P. Stewart, to examine the patients who reported, to note the condition of the operation cavity and to test the hearing. I am greatly indebted to Dr. Stewart for the care with which he carried out this work, and to my secretary, Miss Cadzow, for the preparation of this report.

In order to get at the results in as large a number of cases as possible, I have included in this paper not only the results of Dr. Stewart's work but also the findings obtained at two previous inquiries on this subject—namely, that by Dr. J. K. Milne Dickie of Ottawa<sup>1</sup> and that by Dr. W. T. Garretson of Detroit.<sup>2</sup> These specialists were kind enough to examine patients operated upon by me before 1911 and 1919 respectively.

#### Progress after the Radical Mastoid Operation—with and without Skin Graft: (Total cases, 628.)

Uninterrupted recovery while in hospital, 387; the skin graft was entirely unsuccessful in only 11 out of 377 cases; unexplained fever for several days after operation, causing anxiety but with eventual recovery, 13; tonsillitis, 4; septic rash (surgical scarlet fever), 12; erysipelas, 6; stitch abscess or marked suppuration in posterior wound, 35; dermatitis of external meatus, 3; perichondritis (slight and severe), 10; keloid in scar of incision, 2; giddiness with nystagmus to sound side (serous labyrinthitis), 19; purulent labyrinthitis, 2; facial paresis present on day after operation, 3 cases; coming on more than twenty-four hours after operation, 8 cases; severe haemorrhage from cut edge of external meatus, 3; operation broken off on account of haemorrhage but completed later with success, 1; death following radical mastoid operation, 3 in 628 cases—less than 0.5 per cent.

Shortly after the appearance of a previous paper, by Dr. Milne Dickie and myself, on the mastoid, labyrinthine, and intracranial complications of middle-ear suppuration, one of the followers of Mr. Charles Heath wrote as follows: "The risk to life from Heath's operation is practically nil, whereas the radical mastoid operation boasts a death rate of at least 16 per cent." In a subsequent paper, written in collaboration with Dr. Garretson of Detroit, U.S.A., I tried to make it clear that the fatalities, with two exceptions, had occurred in cases in which labyrinthine or intracranial complications were already present when the patient was admitted to hospital, and that the radical operation *per se* had nothing to do with the fatal ending. The result would have been the same if the modified radical operation had been done in place of the radical. In order to avoid any misunderstanding I am omitting from the present paper all cases in which a labyrinthine or an intracranial complication, such as brain abscess, septic sinus thrombosis, or purulent leptomeningitis, was present on admission.

The three fatalities following the radical operation were as follows:

1. Aural septicaemia or bacteraemia; the cranial blood sinuses were normal *post mortem* (*Journ. Laryngol., Rhinol., and Otol.*, vol. xxxiv, 1919, p. 380).

2. A child fell out of bed on the day following operation, and afterwards became unconscious. Lumbar puncture yielded clear fluid under normal tension. *Post-mortem* examination refused. Cause of death uncertain—status lymphaticus? septicaemia? acidosis? injury to skull? (*Ibid.*)

3. The patient had pneumonia on admission, and was slightly cyanosed and delirious. Death occurred three days after the radical operation on the left ear and two days after the modified radical operation on the right ear. *Post-mortem*—pneumonia.

#### RESULTS.

The cases have been divided into two groups: Group I, with immediate skin graft; Group II, without immediate skin graft.

#### Group I.—Radical Mastoid Operation with Immediate Skin Graft (1916-1925 inclusive).

In this group there were 293 cases; of these, 14 had both ears operated upon, making a total of 307 ears. Of the 307 ears 185 were re-examined, and showed the following results:

**Operation Cavity.**—The cavity was epithelialized and quite dry in 61 (33 per cent.); the outline of the inner wall was retained but one or two small areas of moist pink mucosa were present (want of cleanliness) in 92 (50 per cent.); there was therefore a satisfactory result in 83 per cent. Pus was present with swollen congested mucosa or granulations in 20 (10 per cent.). There was much pus, polypi, and narrow meatus (failures) in 12 (7 per cent.).

**Hearing.**—The hearing was tested in 172 cases. In 27 (15 per cent.) it was much improved, and in 80 (46 per cent.) it was improved—61 per cent. therefore had improved hearing. In 41 (23 per cent.) the hearing was as before operation, and in 24 (14 per cent.) it was worse.

#### Group II.—Radical Mastoid Operation without Immediate Skin Graft (1907-1925 inclusive).

The total number of cases in this group was 268; the re-examinations numbered 157.

**Operation Cavity.**—There was a satisfactory result in 83 (52 per cent.); the operation cavity was epithelialized and quite dry or showing only want of cleanliness—that is, after removal of wax and cast-off epithelium the outline of the inner wall was retained but the cavity showed one or two small areas of pink mucosa on the inner or posterior wall. There was an unsatisfactory result in 74 (47 per cent.)—that is, there was membrane formation or pus and granulations (polypi) in the cavity.

**Hearing.**—This could be tested in only 132 cases when the patient reported. It was improved in 59 (44 per cent.), the same as before operation in 42 (31 per cent.), and worse in 31 (23 per cent.).

#### Stay in Hospital.

**I. Radical Mastoid Operations with Skin Graft (1919-1925 inclusive).**—Of a total of 238 operations the stay in hospital was noted in 221 cases. In the other 17 cases the stay in hospital

could not be noted because the temperature charts had been lost, or the patient had developed scarlet fever or erysipelas and was transferred to the fever hospital. The period was 14 days or less in 108 cases (49 per cent.); 11 to 21 days in 74 (33 per cent.); over three weeks in 39 (only 18 per cent.).

**II. Radical Mastoid Operations without Skin Graft (1919-1925 inclusive).**—Of the 45 cases in this group the stay in hospital was noted in 41. The period was 14 days or less in 11 (27 per cent.); 14 to 21 days in 19 (46 per cent.); over three weeks in 11 (26 per cent.).

**Modified Radical Mastoid Operations—with and without Skin Graft (1907-1925 inclusive).**

A modified radical mastoid operation (either with or without skin graft) was performed in 80 cases during the period dealt with. The results were as follows: uneventful recovery in 55 cases; haemorrhage from the external meatus in 1; the posterior wound suppurated in 11; serous labyrinthitis with recovery, 2; slight cellulitis of auricle, 2; erysipelas, 7; surgical scarlet fever, 1; fatal result, 1. In this last case—a miner who had been injured in the pit and had much coal dust in the tissues of the auricle and skin of the mastoid, with, in addition, almost complete stenosis of the external meatus—erysipelas developed; the patient was transferred to the fever hospital and died there of septicaemia sixteen days after operation.

Of the 80 cases 48 reported for re-examination. (In the majority of the cases an immediate skin graft was applied to the mastoid antrum and cut edges of the bony meatus.)

**Operation Cavity.**—The cavity was epithelialized and quite dry in 26 (54 per cent.); the outline of the inner wall was retained but one or two small areas of moist pink mucosa were present in 16 (33 per cent.); there was therefore a satisfactory result in 87 per cent. Pus was present with swollen congested mucosa or granulations, polypi, and narrow meatus in 6 cases (12 per cent.). These results correspond very closely with those given by Mr. Donald Watson of Bradford,<sup>2</sup> who examined patients on whom the modified radical mastoid operation had been performed at the Royal Infirmary, Edinburgh. Mr. Watson found that out of 50 cases 25 were cured, 17 still had some meatal discharge, and 8 had come to the radical operation.

**Hearing.**—Of the 48 cases the hearing was improved in 31 (70 per cent.), the same as before operation in 10 (20 per cent.), and worse in 4 (8 per cent.). Here again our results correspond with those obtained by Mr. Watson, who found that 64 per cent. of the cases examined by him had good or fairly good hearing after operation, whereas only 35 per cent. had similar hearing before operation.

**Stay in Hospital.**

**Modified Radical Mastoid Operations with Skin Graft (1919-1925 inclusive).**—Of the 23 cases in this group the stay in hospital was noted in 27, as follows: 14 days and less, 12 (44 per cent.); from 14 to 21 days, 10 (38 per cent.); more than 21 days, 6 (18 per cent.).

**Modified Radical Mastoid Operations without Skin Graft (1919-1925 inclusive).**—The duration of the patient's stay in hospital was noted in 22 of the 23 cases in this group, as follows: 14 days and less, 8 (36 per cent.); from 14 to 21 days, 10 (45 per cent.); more than 21 days, 4 (19 per cent.).

**III.—PROFESSOR HEINRICH VON NEUMANN, Vienna.**

MASTOIDITIS can be considered from many points of view, since the lesions are both various and variable. As its clinical aspect is indefinite, so is its diagnosis often uncertain, the latter being often a matter of opinion rather than a question of objective signs.

Further, as we are apt to include in the term "mastoiditis" both its diagnosis and its operative treatment, our ideas as to its meaning become even more vague, particularly as the indications for operation vary in relation to both the surgeon and the locality in which he lives.

A disquisition on the clinical aspect of mastoiditis is unnecessary, but I think it is worth while to describe our procedure once the disease is diagnosed. In the first place, I would urge that we should endeavour, by pathological, anatomical, and clinical research, to treat successfully acute inflammatory affections of the middle ear by conservative means. Up to the present, and in spite of extensive histological research, we have no definite conception of the conditions demanding operation, inasmuch as we are unable to describe the conditions under which spontaneous cure may result.

Acute otitis media is an acute inflammation of the mucous membrane of the tympanic cavity; it probably always extends more or less to the cellular structure of the mastoid process. The inflammation in the membrane lining

the mastoid cells differs in character from that affecting the mucous membrane of the middle ear, since the former is not a true mucous membrane and should not be so described. Its histological structure is not yet decided, but the modern view is to regard it as a muco-periosteum or endosteum.

In the majority of cases of acute otitis media the mastoid inflammation resolves, and the disease is limited to the middle ear. At times, however, there is a progression of

FIG. 1.—Early mastoiditis. (a) Inflamed mucous membrane of air cells; pus in cavity. (b) Adjacent inflammatory changes. (c) Osteoclasia.

inflammation in the mastoid cells, and their bony walls become involved. We are then confronted with a true osteitis with which it is necessary to deal by operation. As to the factors on which this extension of inflammation depends and progresses we can only speculate. Amongst others are certainly the kind and degree of virulence of the infection, the so-called individual power of resistance, and the anatomical and histological structure of the temporal bone itself.

We have endeavoured to determine the processes concerned in the progress of mastoid disease, and have, in this investigation, examined tissues removed during operation. While such material has been taken from cases both in the early and later stages of disease, we have only been able to determine therefrom an approximate idea of the histological conditions preceding mastoid osteitis.

Although we have obtained much positive knowledge, the inferences gathered from the data are not conclusive. Fig. 1 shows an early condition of mastoiditis (osteitis). The membrane lining the cells is thickened in many places and undergoing cell proliferation. In the cell spaces themselves there is free pus. In the neighbouring canal system osteoclasts are seen which have already destroyed the struc-

FIG. 2.—Mastoiditis in third week. (a) Thickened lining of air cells with (a') proliferation into the exudate at (b).

ture of the bone. We are thus examining a specimen at a time when the cells are filled with pus and a destructive osteitis has spread in the canals. The spontaneous recovery of such a condition is both questionable and unsupported by histological research. In Fig. 2 we see an intermediate stage in which the cell proliferation of the membrane lining the pneumatic spaces has proceeded a stage further and has invaded the inflammatory exudate, which is already

becoming organized. Still later, in Figs. 3 and 4, there are outgrowths of rapidly formed spongy bone which are filling the original cavities of the pneumatic cells. The more advanced the disease the more this irregular growth of bone is evident.

There is no relation between the clinical symptoms of mastoiditis and its histology. There may be the most severe

FIG. 3.—Mastoiditis in sixth week. (a) Newly formed bone in thickened lining of air cell contrasted with lamellar structure of original bone (a').

clinical manifestations associated with insignificant pathological changes, or, on the other hand, an almost complete destruction of bone with an almost complete lack of symptoms, especially if the *Streptococcus mucosus* is responsible. Mastoiditis, therefore, is a clinical condition not lending itself to accurate definition, and the indications for its operative treatment remain, as has been already stated, largely a matter of individual opinion. Radiography does not assist us in deciding upon the stage of the disease, since even the presence of an exudate in pneumatic cells will cause a shadow and give no definite information on the state of the bone. The best time to operate is when the inflammatory process has subsided and become restricted, and before complications have occurred. The period at

FIG. 4.—Columns of newly formed bone in lumen of cell.

which such complications are most likely to occur is best determined by a statistical investigation from one clinic.

From a series of 800 cases of acute otitis media which we have collected during the past six years (arranged below in tabular form) it appears that the occurrence of complications has a general relationship with the duration of the disease. Although it is true that a large percentage of complications occurs during the first week (8 out of 14 cases, of which 3 patients died of meningitis, in a further 3 the sinus wall was involved, and in 2 sinus thrombosis had occurred, with ultimate recovery), the greatest number supervene during the sixth week and after. We therefore should not postpone operation until this time; most authors agree that operation should not be delayed beyond the third or fourth week of the disease. Operation at an earlier period—that is, in the second or even the first week—will generally be declined, and as a surgical reason against the

so-called "early" operation, the lack of obvious delimitation of the inflammatory process is urged.

It is very difficult to distinguish between diseased and healthy bone, and the possibility thus exists of disseminating the disease and infecting portions of the bone hitherto healthy, thereby prolonging the after-treatment and risking a second operation either for a recurrence of the disease or for the repair of a retro-auricular fistula. A small group of otologists holds the opinion that the early operation should be advised, and recommends it in the earliest stages of the disease with a view to preventing the development of complications. It is obvious that the earlier operation is done the larger will be the number of operations performed with their ensuing accidental risks, such as wounding of the sinus, the dura, the brain, or the labyrinth; those associated with the anaesthetic; the possibility of infecting an exposed sinus; the development of erysipelas, pneumonia, and so on. It is doubtful if the mortality will be decreased by a general acceptance of the proposals for early operation. A still smaller group defer operation until the sixth week—that is, of course, if no alarming symptoms, such as high temperature, rigors, or cerebral disturbances, demand immediate surgical relief. The statistics, however, of these late-operated cases appear to us to give too large a number of complications, especially perisinus and extradural abscess.

We have based our ideas as to the indication for operation on the result of statistical inquiry, and indeed this is the only practical method when clinical symptomatology fails. According to our statistics, then, as we have shown, it would appear that the third and fourth weeks are the times of election for operation; but this, too, is a statement which requires qualification, in that its accuracy is influenced by whether or not the case has been under observation since the onset of the disease; in the former the mortality is only 1 per cent. This reaches 5 per cent. in those cases coming to operation at the same period but which have not been previously under observation.

Removal of bone in order to give us an idea of its condition before operation is neither practical nor would it be of much assistance, since we do not know under what conditions a spontaneous cure may result. As is seen in the illustrations, there is an active process of regeneration in progress at the time we usually operate, and the longer the disease has existed the greater the new bone formation. What we remove at the operation with chisel and curette is for the most part new bone, as histological examination shows. We therefore destroy and remove vast masses of regenerating tissue. The paradox of removing regenerating bone in order to cure osteitis is more apparent than real.

The existing inflammation is responsible, first, for bone destruction, and secondly, for its regeneration. Therefore, destruction and regeneration are proceeding *pari passu* and in close relation with each other, and consequently we find healthy unaffected bone, necrotic bone, and new bone at the time of operation. It is impossible to say, however, by inspection of the tissue what is healthy or what can recover; the new bone, deficient in calcareous matter, is soft to the curette, and for the greater part embedded in granulation tissue, while the infected bone is as hard as, or even harder than, normal.

On these considerations, and on the complicated arrangement of the pneumatic cells of the temporal bone, depends the failure of many operations. The pneumatic structure and the placing of the mastoid cells has always been a

matter of zealous investigation by anatomists, embryologists, and especially clinicians; the work of Cheate comes prominently before the mind in this connexion.

The expert operator, benefiting by an experience bought with great pains, knows when he has removed all that is necessary, but the tyro is not so easily able to recognize when he has completed a mastoid operation. We have therefore permitted ourselves to frame a definite technique for didactic purposes in order to prevent the operator young in experience from leaving behind diseased tissue.

After opening the antrum we remove all cells in the neighbourhood of the zygomatic process, which often appear separated from the main collection of cells by a definite partition, and may be easily overlooked. Then we open up the cells which lie on the posterior aspect of the mental wall, along the course of the Fallopian canal (the retrofacial cells). It must not be forgotten that this group of cells often extends behind the horizontal semicircular canal beneath the labyrinth, and, further, that the retrofacial cells are in connexion with the peribulbar cells, and that these latter are in continuity with the medial and lateral cells in the neighbourhood of the digastric groove and the apical cells. Lastly, we deal with those cells around the sinus in the posterior portion of the mastoid which we describe as "marginal cells"; through this area run one or two emissary veins. Upwards these cells are in

We do not hide from our patients and their friends the fact that mastoiditis is not to be regarded as harmless, or an operation without risk; we explain that it must entail a certain risk, and that the question of a neat scar is of secondary importance, and should not in any way influence the thoroughness of the operation. After all, the operation scar lies behind the ear, and can neither be seen from the front nor in profile, and in the case of women can readily be covered by an arrangement of the hair.

To recapitulate a few points: By the systematic removal of the cells as described above we are relieved of any doubt as to the extent of the disease, what bone should be removed or what may be left; it is scarcely possible to overlook an infected cell which might be the source of complications later.

Inasmuch as the marginal cells are removed, we have naturally to take away the cortical portion of the bone behind the sinus as deeply as possible—sometimes to below the knee of the sinus—and thus a somewhat wide, open funnel-shaped cavity results, which can often be improved by removal of the outer portion of the posterior mental wall.

The apex of the mastoid process is not usually resected, unless the disease makes this imperative; incidentally such a resection is responsible for most indrawn and visible scars, since the origin of the sterno-mastoid is interfered with.

The post-operative progress is usually uneventful, if we

FIG. 7.

FIGS. 5, 6, 7.—Stages in operation.

connexion with the cells of the petrous bone, which latter are interposed between the lateral sinus and the dura of the middle fossa; they are often of considerable size, and extend far backwards.

In the pneumatic type of mastoid all these groups of cells are more or less developed, and according to our method of operation systematically sought for and opened, leaving a characteristic operation cavity with relatively smooth boundaries, in which the bony covering of the sinus stands out in relief. If the resulting cavity is too narrow its width may be increased by removal of the outer boundary of the posterior mental wall.

Since we adopted the above procedure in our clinic no secondary operations have been necessary. The operation cavity left after the method of operating described is naturally larger than the usual one, and the question of after-treatment is raised; this will, of course, be of longer duration, but we consider this to be counterbalanced by the result in view. After-treatment is prolonged if the wound is left quite open, as it must always be if the sinus or dura is exposed; it is shorter if the upper part of the wound is sutured, and this procedure will also give a neat-looking scar.

It is said that the after-treatment is concerned in the possibility of recurrence. We have seen no difference in this respect between our method and the usual method of operation. In the repair of a large or small operation wound in the mastoid the cavity is filled with fibrous tissue consisting more or less of a system of spaces in communication with the antrum. This is followed by a new growth of bone which, after a thorough operation, is very slight, and in no way corresponds to that production of bone resulting from inflammation.

The larger scars resulting from this operation are a disadvantage, and compare unfavourably with those left after a simple anterotomy. Work on plastic operations and efforts towards closing the operation wound would almost give rise to the impression that the whole problem of mastoiditis is referred to the cosmetic appearance of the scar!

except those cases in which exposure of the sinus or dura may render the course more difficult.

It should be mentioned that the earlier operation is undertaken the more probable are complications of the soft parts; if, however, undue respect is not paid to the cosmetic result such complications are rare. It is wise, therefore, to leave the wound widely open, especially in its lower part, where such undesirable sequelae usually begin.

It has been urged by many that the possibility of a retro-auricular antral fistula is a disadvantage of our method. As a fact, we but rarely meet with them. In our view a large mastoid wound is not responsible for a fistula. Rather is it to be referred to an incomplete operation, the leaving of unopened cells and areas of diseased bone; such residua cause long persistence of a discharging wound and the ingrowth of epithelium into its cavity.

It may not be out of place to describe the method we employ in closing a retro-auricular fistula, as it has given us infinite satisfaction. (See Figs. 5, 6, 7.) We remove the old scar, reflect the skin forwards and backwards, and fashion two periosteal flaps with bases below. These flaps are laid into the freshened bony cavity and united with a few sutures; the cavity is further filled up with flaps from the temporal muscle, varied in size and shape to fit individual cases. The skin is united and a small gauze drain left in the lower angle of the wound. The dressing is changed on the fourth day, and the gauze drain removed and not replaced. The result is favourable whether the stitches hold or not; healing should follow by first intention; if small pockets remain in the wound the closing of them is only a matter of time.

In this address I have attempted to give our attitude towards the question of mastoiditis, based on our experience for the last few years. As in other questions in medicine, we do not claim that the last word has been spoken, but we propose to persist in this method and practice until possibly other methods and further research compel us to adopt other treatment.

## GENERAL DISCUSSION.

Mr. LIONEL COLLEDGE (London) thought that it ought not to be necessary to remind aural surgeons that they could not disregard the well established principles of surgery by leaving dead spaces undrained and by neglecting to arrest haemorrhage, proceedings which were, however, still recommended and practised. It was such a common experience for patients to present themselves with an abscess bulging out a post-aural scar in cases where the presence of stitch marks showed that the wound had been sutured after a Schwartz operation performed several months or perhaps a few years earlier, that, however cynical this remark might sound, it was fully justified by experience. On reopening such wounds a cavity with rough overhanging edges of bone was found full of pus and septic granulation tissue, showing that healing had never occurred. If the operator wished to close the wound after a Schwartz operation it was much better to do so as a secondary measure when the cavity was lined with healthy granulations at the end of five to ten days, and then only if the stitches could be so applied as to obliterate the cavity. This was possible if the cavity was not too wide. Bipp applied to the bone was useful, but there was no magic in it, and an occasional apparently brilliant result did not justify the departure from sound principles. If the wound was stitched primarily the lower end should be left wide open and drained. A better method if the cavity was large and could not be obliterated, and especially if it was heavily infected, with a sloughing lateral sinus or dura mater, was to adopt Carrel's method of wound treatment—a method particularly suitable for bone wounds. The wound was left wide open and the cavity was filled with half-inch ribbon gauze which had been soaked in eusol; into the middle of this an india-rubber tube closed at the lower end with a silk ligature was introduced. There should be only one fairly large hole in the side of the tube, just above the silk ligature, and the tube should be so arranged in its nest of gauze that the hole looked directly inwards. A gauze dressing with a round hole for the passage of the tube and a crescentic opening for the auricle was applied over this. The tube should be just long enough to project outwards between the upper folds of the bandage. The skin should be smeared with vaseline to protect it from the action of the eusol. With a small syringe the nurse injected a drachm of eusol down the tube every two hours. This dressing should be changed daily. As it was wet it did not stick and was painless, and it was gratifying to observe how in a few days sloughs disappeared and the cavity became quickly obliterated by bright red firm granulations. If the lateral sinus had been opened and obliterated with packing the constant soaking made the removal of this a very simple matter. There was a further advantage that the epithelial edges appeared to spread in very rapidly under the influence of eusol. When the cavity had become quite shallow it was sufficient to dress the granulating surface with boric powder to prevent the dressing from sticking to the surface.

In the management of the cavity left after the radical operation Mr. Colledge was among those who preferred to graft. If there was any contraindication to grafting such as an opening into the labyrinth and exposure of the facial nerve, it did no harm to smear the cavity with a little bipp and pack it lightly. The packing was removed in five or six days, and thereafter the cavity was filled daily with boric powder. The worst results were produced by prolonged packing with ribbon gauze. Carrel's method did not lend itself unless the post-aural wound had been left open, in which case it was very useful, provided that a large mental flap had been cut. The speaker believed that whenever possible the cavity should be lined with a graft, which secured healing more rapidly, and with more certainty; the hearing afterwards was, in his opinion, better. In some cases of double radical operation in which only one side had been grafted he had always found that the result was better and the hearing better on the side grafted. The graft might be applied primarily at the time of the operation, but he thought it was safer and more satisfactory to do this at the end of

about a week. Of the various ways the easiest and most effective was that of Mosher. The Thiersch graft was spread over a hollow cone of gauze impregnated with paraffin wax. The paraffin wax made an exact cast of the cavity, so that the graft fitted accurately; nor did it adhere to the graft, so that when the cone was withdrawn in a week's time the graft was left in perfect position. If the post-aural wound had been left open it was very easy to do this, and there was no difficulty if it had been closed, because the cone, being hollow, could be made to collapse and be withdrawn through the meatus. A few days later the superficial layer of the graft was cast off as a slough, leaving the bone completely covered with epithelium. At the present time Mr. Colledge believed that this method was superior to all others.

Mr. CHARLES HEATH (London) said that at the Downs Hospital for Children, which was, he believed, the largest ear hospital in the world, they aimed at the prevention of those calamities which could not be avoided when the operations under consideration were adopted; these operations were Schwartz's so-called "simple" mastoid operation and Stacke's "radical" one. He hoped to explain how these calamities could be prevented, as deaths from appendicitis had been. An appended note to an article by Dr. Anthony Wrench, entitled "Some guiding principles in the post-operative treatment of mastoid disease," was as follows:

"These remarks apply to the radical and Heath's conservative mastoid operations. The Schwartz operation is now never performed at the Downs Hospital, as this method of dealing with mastoid disease has not infrequently been found to be followed by dangerous recurrences. The dressings also are more painful. The scar is unsightly. And, the worse fault of all, the site of the aural cavity and the drumhead are left practically inaccessible."

There were thus four counts in his indictment of Schwartz's operation. Mr. Heath considered that Schwartz operation wounds, whether left open or sewn up, were liable to dangerous recurrences, which he had seen at the Downs and at fever hospitals. They brought about conditions as bad as or worse than those existing at the time of the original operations—namely, pus in the antrum and under the skin behind the ear. In consequence of a death, due to septicaemia and meningitis, resulting from a recurrence after a Schwartz operation performed at a seaside town, which came under observation at the Downs Hospital, he had felt constrained to point out the dangers of recurrences after Schwartz operations and their absence in recurrences after conservative ones. He was glad, therefore, to learn, from Dr. Wrench's article, that Schwartz operations had been given up. Further, the surgeons at this hospital had experience which was unequalled elsewhere and justified a decided attitude regarding this or, indeed, any other mastoid operation. Were it not that the "after-treatment and results" of this operation were down for discussion and that they saw sad recurrences after its use, he would have imagined that it was obsolete and that he was "flogging a dead horse." Twenty years ago (1906) Dr. Percy Jakins, surgeon at the Central London Ear and Throat Hospital, after seeing the conservative operation performed by Mr. Heath at the Throat Hospital, Golden Square, said: "Your operation will take the place of all Schwartz and most of the Stacke radical operations"; he had performed no Schwartz operations since. The senior aural surgeon at one of the large teaching hospitals in London had recently informed the speaker that he never performed any mastoid operations except by the conservative method.

Painful dressings were complained of when the Schwartz wound was left open—an important matter at the Downs Hospital, with 150 children who could not tolerate them. The after-treatment of mastoid operations was an art, and the operative technique should be designed to facilitate it; this had been done in the conservative one. For example, a baby, aged 3 months, with aural discharge and polypus operated on by the speaker only required four subsequent dressings. The after-treatment at the Downs Hospital allowed of one person dressing over 100 patients in a morning; after the conservative operation these dressings were performed more easily than after any other, because

the antrum—the only part packed—was a cavity of remarkably little sensibility."

If after Schwartz operations the wounds were left open, disfigurement must result; Mr. Heath had known plastic operations needed to remove them. An operation requiring fresh incision, close to the ear, a conservative mastoid operation was performed; secondly, the old scar (and suppurating sinus if there was one) was excised and the wound was sown up; in this way danger and disfigurement were both removed.

An inaccessible antrum was the great cause of danger from recurrences after Schwartz operations, because this cavity was not open to the air, as it was after the conservative one. Indeed, in the technique of the latter the dangerous antrum was cut off from the middle ear altogether; it became a part of the outer ear, was always open to the air, and was therefore safe—a surgical rearrangement of the hinder end of the middle ear, which Mr. Heath had devised to ensure the future safety of the patient by providing a permanent safety-valve.

Other indictments of the Schwartz operation had to be added, including the prolonged after-treatment, as compared with the conservative operation. Fourteen days after the performance of conservative mastoid operations on two nurses the patients were working in their wards; neither had an ear dressing of any kind, not even a small piece of wool. In that short time the perforation in the drum of each had healed; their ears were sound and safe. Quick recoveries occurred in the majority of these cases, and were equally rapid when both ears had undergone operation at one sitting by this method.

In the Schwartz operation there was also the liability of dislocation of the incus bone, causing deafness, in consequence of the surgeon's inability to locate it precisely, because the tympanic ring and drumhead were not exposed for this purpose in Schwartz operations, as they were in the conservative one. This would explain some of the cases of deafness following Schwartz operations hitherto inexplicable.

Suppuration within the sheath of the temporal muscle occurred both in Stacke's (radical) operation and in that of Schwartz because the sheath was opened during these operations; since aural discharges before and after operations on the ear were septic, the exposed muscle might become involved in the septic process. The opening of the sheath was avoided in the technique of the conservative operation; in consequence of this and its other advantages this technique was largely followed, at the Downs Hospital, in every mastoid operation performed there, even the radical ones.

The Schwartz so-called "simple" mastoid operation was too simple; it was a crude proceeding, like the earliest abdominal operations, and a disfiguring emergency measure hurriedly devised to save life by providing drainage for an acute abscess in bone in a dangerous locality. It made no provision against an equally or more serious recurrence, and might not assist in the preservation of the hearing; it was not devised for this purpose. The objectionable features inseparable from Schwartz's operation had all been overcome in the conservative one.

The present position of Stacke's (radical) operation could not be maintained, because of the deafness it left, and because timely conservative operations did not leave deafness. In addition to the handicap of deafness, patients were so long in hospital after radical operations that the output per bed was small, whereas patients were usually home in a week or less after mastoid operations on conservative lines. With the present accommodation at the Downs Hospital they could turn out from five to ten times as many good ears after conservative operations as they did now if patients were sent in before their ears were damaged by disease. This would entail more operations, but the timely performance of operations had proved so effective and safe in appendicitis that it was satisfactory to know that mastoid operations could be equally so. As a rule that mastoid patients were out walking three days after Mr. Heath's patients were out walking three days after mastoid operations, and were not so ill as those who underwent the removal of tonsils. The conservative operation, therefore, could justly be regarded as a small matter

compared with the great importance of saving hearing and ending the futile time-wasting out-patient treatment.

With regard to treatment by ionization, Mr. Heath said that this not only failed to cure (because of physical difficulties due to the anatomy of the ear), but it failed to prevent the destruction of hearing by disease. Its general use, therefore, for this ear disease was not justified. In a shorter time than the ionization treatment was spread over discharging ears could be cured by conservative mastoid operations. There were aural conditions, however, in which ionization was occasionally useful. Mr. Heath used it, not before, but after mastoid operations in cases of long-standing disease which were slow in healing, because after operation the ear could be completely filled with the ionizing fluid; before operation this could not be done, hence the failure of the treatment then. The ears which were likely to derive benefit from ionization alone were the very badly damaged ones, which would never be sound again even if dry.

Mr. E. D. D. Davis (London) said that an experience of over 500 mastoid operations had shown that the amount of after-treatment depended very much on the efficiency and type of operation performed; the less the after-treatment the better and more efficient the operation. In the case of the radical mastoid operation performed for suppuration of long duration there were certain details which helped to eliminate after-treatment. It was important, at any rate in the case of children, that unhealthy tonsils and adenoids should be removed before operation, and as a preliminary to this the mouth and teeth should be put in order. In a few cases where this had been done the mastoid operation had been rendered unnecessary. The mastoid operation should be performed as early as possible after the more conservative treatment had failed, and the less radical the modified radical operation described by Logan Turner and others. The removal of a large area of bone was rarely necessary, and the lateral sinus and middle fossa dura should not be deliberately exposed unless signs and symptoms demanded this. The middle ear and auditory meatus should be treated as gently as possible. Curetting was decidedly harmful, and after removal of the malleus and incus the remainder of the drum should be left to cover over the orifice of the Eustachian tube.

The continued Eustachian discharge was the disadvantage of many radical mastoid operations, and the speaker had tried every known form of treatment to close the Eustachian tube, with little success; he had come to the conclusion that in those cases in which there was no Eustachian moisture a false membrane or scar had sealed the orifice of the tube, and this scar formation was helped by leaving the remnants of the drum. Grafting failed to close the tube, and he did not think grafting was worth the trouble except in cases where there was a large cavity and extensive removal of bone. The method of treatment he preferred was to pack loosely with gauze soaked in fluid bipp the aditus and opening in the posterior meatal wall left by the cutting of the flap. The ear was dressed as little as possible, and then only under strictly aseptic conditions. The first dressing was done four to five days after operation, when the gauze packing was changed, and subsequent dressings followed not more than once every other day. When the post-aural wound had healed the outer dressing was left off and the patient went home at the end of a fortnight, being told to keep the meatus clean by gentle mopping with boracic lotion, and to avoid plugging with cotton-wool so far as was practicable. Mr. Davis was convinced that hydrogen peroxide spirit drops, or any other drops, did more harm than good. The patient was seen once a week until the mastoid had healed, which, in the simple or Schwartz operation he had been in the habit of performing a very complete exenteration of all the cells, like that described by Professor Neumann, also of incising the drum to drain the middle ear. The wound was closed with the exception of a small drainage tube, to be removed at the end of forty-eight hours. He strongly condemned the popular packing of the wound, which he considered unnecessary. Complications occurred,

not as the result of a closed wound, but owing to the unopened suppurating cell. He was also opposed to the cutting of a meatal flap for drainage through the meatus, because stenosis of the meatus frequently followed, healing was delayed and a secondary sepsis occurred, too frequent and painful dressing was required, and the result was certainly no better than that of the simple mastoid.

Mr. HERBERT TILLEY (London) said that much of the pain caused by removal of the first dressing could be obviated by inserting a layer of oil-silk between the edges of the skin wound and the gauze strip when this material was used for plugging the wound. He quite appreciated Mr. Jenkins's apprehensions as to the possible dangers involved by primary and complete suture of the skin wound after the Schwartz operation. Some ten years ago Mr. Tilley had shown at the Otological Section of the Royal Society of Medicine a series of ten consecutive cases in which primary suture had been performed; in one patient the lateral sinus had been exposed by the disease. In no case was there any complication, and the patients were about in a fortnight, with a completely healed scar, intact tympanic membrane, and hearing as good as resulted from any other type of operation. It was essential to success that every infected cell should be removed as far as the naked eye could judge. The bony wound was freely cleansed with hydrogen peroxide, then with alcohol, and finally and freely smeared with bipp before suturing. A large number of patients had been operated on by this method by Dr. McNab of Johannesburg and Dr. Guthrie of Edinburgh. For the last few years Mr. Tilley had inserted a narrow bundle of silkworm-gut strands into the lower end of the wound; he removed them at the first dressing and then applied firm pressure over the bony wound. This seemed to obviate any possible danger in case there had been failure in removing all sepsis at the time of operation, and the delay in primary union was practically negligible. He only wished to maintain, in favour of the method, that it was a great time-saver of after-treatment.

Mr. NORMAN BARNETT (Bath) thought that a very advisable procedure in the after-treatment of the operation for acute mastoiditis was to wash out the middle ear through the aditus before the patient left the operating table. In this way a large amount of pus and debris was got rid of and healing was much more rapid. His experience with bipp and/or primary stitching of the posterior wound was not encouraging. He considered that the better treatment was to stitch up the upper part of the wound, to leave drainage, and to pack with iodoform gauze, or, in the case of a very foul condition, to fill the space with iodoform emulsion as well as packing it with gauze. In the later stages a sinus might refuse to heal, and for this he found that weak iodine was of value.

The object of the modified radical operation was to save the hearing apparatus of the middle ear; it was therefore necessary that this should be rendered as healthy as possible, and in his experience this was best achieved by washing out the middle ear through the aditus, which was reached by a large flap made in the posterior soft wall of the external auditory meatus. Through this a nozzle was passed into the obliterated mastoid-antrum, and from an attached bag air was blown through the aditus into the middle ear and out through the opening in the tympanic membrane, carrying with it a considerable amount of debris. This was followed by washing out the middle ear gently with bland substances, such as normal saline or colloidal silver, or a vapour of iodine and camphor might be passed through. In this way all disease products were gradually driven out from the middle ear and a healthy condition of the structures was promoted; there was then a very great likelihood of healing with restored function. Irrigation or inflation was continued for a varying period, according to the nature of the case and the amount of diseased tissue to be cleared. After this, in the great majority of his cases, the tympanic membrane healed even where it had been widely burst or was almost non-existent; this was true at almost any age. He had been greatly surprised to observe, even in elderly subjects, that the

tympanum might become wholly closed in by a new tympanic membrane growing from an insignificant margin. It was a wrong attitude towards such a method of modified radical operation to suggest that it was simply an alternative draining through the external auditory meatus instead of behind. One of the great objectives of the method was to facilitate treatment of the middle ear afterwards, and to obviate the removal of this important part of the hearing apparatus.

Dr. W. JOHNSON HORNE (London) had found the opening papers refreshing inasmuch as after going out in various directions for new treatment these had brought them back to where he started from thirty years ago. It was impossible to lay down hard and fast rules for the treatment of the mastoid antrum. He was in favour of a "large meatus," and he had seen advantage in meatal drainage in combination with post-auricular drainage with a small drain of gutta serena tissue. At the same time he was not in favour of completely closing the lower part of the post-auricular incision. After primary suture of the upper part, secondary suture was not required. The drooping auricle, or displacement of the auricle forwards, could be prevented by suitable bandaging. That was another reason for doing the dressings personally. He agreed that sepsis, when it occurred, was due very often to leaving the after-treatment to others. At times it was difficult for the surgeon to keep the after-treatment entirely in his own hands. A general anaesthetic for the first dressing was not required and was best avoided; it was apt to create an erroneous impression that a second operation had become necessary, in spite of the assured success of the first. The fewer the drops, the more simple and the less irritating the solutions or applications used, the better. Last, but not least, that unaccountable hurry to get the patient out of bed on the third or fourth day, and back at work by the end of the week, must be condemned. After a simple or radical mastoid operation a fortnight in bed should be the minimum amount of rest allowed to a human being who valued health and the organ of hearing.

Mr. ANDREW WILLIE (London) agreed with Mr. Jenkins's procedure and reproached the use of antiseptics during and after operation. He disapproved of packing a radical mastoid cavity, his own practice being to irrigate it gently each day with an unirritating lotion.

Mr. C. A. S. RIDOUT (Portsmouth) left a wide posterior opening in mastoidectomy, particularly when severe infection was present. After about ten days secondary suture might be performed. He had seen many entirely successful results of the modified radical operation, and considered that careful after-treatment had an important bearing on a subsequent perfect result.

Dr. SCOTT STEVENSON (London) said his practice was to perform the Schwartz operation in acute mastoiditis and to suture the wound. This did not imply that the wound was to remain closed for ever; if necessary the sutures were removed.

Dr. W. S. SYME (Glasgow) thought the success of the Schwartz operation depended very largely on the thoroughness with which the cells were dealt with. He believed in removing the tip of the mastoid, and was grateful to Professor von Neumann for drawing attention to the retrofacial recess.

Sir WILLIAM MILLIGAN (Manchester) considered that, taking cases as a whole, it was better to have the wound open after a Schwartz operation. His experience was that hearing improved in many cases after the radical operation, and he held that an important item in procuring a good result was not to send the patient out of hospital too soon. He agreed that grafting shortened the after-treatment materially, robbed it of pain, and allowed the patient to go about his life again much sooner than he could otherwise do.

Mr. NORMAN PATTERSON (London) asked Professor von Neumann whether, in doing a modified radical operation under a local anæsthetic, it was his practice to remove the incus. Professor von NEUMANN replied that in about 80 per cent. of cases of chronic otitis the incus was disarticulated from the stapes, and in these circumstances he removed it; its removal did not adversely affect the hearing.

Mr. G. J. JENKINS (London), in reply, supported Professor von Neumann in advising meticulous care in the opening up of all cells of the mastoid and neighbouring regions in operations for acute mastoiditis. He was familiar with the group of cells between the dura of the posterior fossa and the facial nerve, and examples of this group could be seen in Mr. Cheate's collection in the Royal College of Surgeons. He knew of two abscesses of the cerebellum, just above and external to the jugular foramen, which seemed to be associated with the infection of this group of cells.

Mr. J. S. FRASER referred to tubal catarrh being responsible for the continuation of discharge after a radical mastoid operation, and spoke of the impossibility of curing it. His own experience of primary closure in a simple mastoid operation, undertaken against his wish and only from motives of dire necessity, had been followed by a fatal result.

## PHARYNGEAL AND OESOPHAGEAL DIVERTICULA.

BY

WILLIAM HILL, M.D.,

Consulting Surgeon, Diseases of the Ear, No-e, and Throat,  
St. Mary's Hospital, London.

THERE is probably no group of lesions in the descriptions of which so much ignorance and inaccuracy have been so frequently perpetrated and perpetuated as in those appertaining to the various etiologically, topographically, and clinically distinct types of diverticula of the pharynx and of the oesophagus. The taking stock and the straightening out of this subject which I have undertaken are long overdue. Pouches originating in the former region, the pharynx, are almost invariably described under diseases of the oesophagus, and with great frequency they are actually, but wrongly, designated oesophageal pouches and occasionally pharyngo-oesophageal pouches. They are neither. Moreover the textbooks, both general and special, ignore at least four separate varieties of pouch which I shall emphasize later—two forms being truly of pharyngeal, and the other two of oesophageal origin.

The following is a classification of the various species of diverticula of the upper alimentary tract which, whilst presenting some features more or less in common, are for the most part etiologically, patho-anatomically, and in their clinical signs and symptoms separate and unrelated entities. Their presentation in tabular form will help to clear away many of the prevalent misconceptions which have obscured in the past and still obscure these lesions.

### A. Pharyngeal in Origin.

1. Congenital centrally placed anterior diverticula.
2. Congenital lateral post-faucial diverticula. (Synonyms: *Aeroceles*; *iranchial diverticula*.) The mouth of these pouches is usually in the region of the palato-pharyngeal fold, but may be lower down in the glosso-epiglottic and in the pyriform fossae or near-by these. These pouches are due to embryonic developmental errors in the region of the branchial clefts. They form swellings on one side of the neck and of considerable size when of long standing. They contain air and mucous secretions, but rarely food, as the orifice on the lateral wall of the pharynx is usually so small.
3. Deep pharyngeal pressure diverticula or pouches. (Synonyms: *Pharyngeal pulsion pouches*; *Rokitansky's pulsion pouches*; *Zenker's pulsion diverticula*.) The mouth of these pouches is invariably situated posteriorly and mesially at the line of junction of the upper oblique and lower transverse sphincteric fibres of the inferior constrictor muscle. They are fairly common. (*Pulsion pouches of the pharyngo-oesophageal junction—the Grenz diverticula of Rosenthal—and of the Lannier-Hackerman area at the upper end of the gullet are a figment of the imagination of untrustworthy and incompetent observers, and no post-mortem confirmation is obtainable*

of their occurrence. Most authors misleadingly include these alleged varieties, but on insufficient evidence and faulty observation.)

### B. Oesophageal in Origin.

4. Traction diverticula, situated mostly more or less at the level of, posteriorly to, the hilus of the lung—for example, to the bronchial glands area (*Rokitansky*) They may, however, occur elsewhere—for instance, in the supraclavicular gullet (*Chevalier Jackson*), and in the epiphrenic segment not far from the level of the diaphragm (*Starck*, *Luschka*, *Arnold*, *von Brosch*, *Halstead*, *Hurst*, and others). (Synonym: *Rokitansky's traction diverticula*.) They are not really rare, apparently, though not often diagnosed during life, as symptoms are usually absent.

5. The traction-pulsion diverticula of *Starck*. In these a pouch originating by traction subsequently becomes expanded by food pulsion. Food lodging in these pouches was held by *Rokitansky* to be a frequent source of septic mediastinitis and various suppurative diseases of the lungs and pleura of hitherto unexplained origin. Such sequelae, however, have not been considered common by subsequent authorities.

6. *Leugart's* post-bronchial ledge pulsion diverticula, situated behind the level of the left bronchus above *Leugart's* ledge. These diverticula are rare.

7. Epiphrenic pulsion diverticula, situated in the lower third of the gullet not far above the diaphragmatic level (*Zenker*, *Bensaude*, *Kraus*, *Starck*, *Hurst*, and others). They are rather rare.

8. Dissecting diverticula.

9. Diverticular sinuses.

## CONGENITAL CENTRAL ANTERIOR DIVERTICULUM OF THE PHARYNX.

Considering the frequency of anterior centrally placed fistulae, sinuses, and cysts at the base of the tongue (second branchial cleft survivals) diverticular *aeroceles* might be expected to occur there, and also in connexion with the third and fourth branchial clefts lower down; but the only recorded instance, probably of this nature, with which I am acquainted is a case recently reported by *Hurst*, in which there was stated to be a central opening on the posterior pharyngeal surface of the cricoid plate with a diverticulum passing down between the trachea and oesophagus; this filled up with food, causing dysphagia. This could evidently be capable of surgical extirpation by a lateral incision in the neck. Although of congenital origin it was evidently increased in size by food pulsion. This exceptionally, if not uniquely, placed diverticulum was discovered by radiography, to which recourse was had to explain the dysphagia.

## CONGENITAL LATERAL PHARYNGEAL DIVERTICULAR SINUSES AND AEROCELES OF ABNORMAL BRANCHIAL CLEFT ORIGIN.

Branchial fistulae opening both externally and internally, and branchial sinuses ending blindly in the neck, opening either externally only or, less commonly, internally only, are by no means rare lesions, and are well known to be due to embryonic developmental irregularities in the devolution of the branchial clefts; cysts, dermoid and otherwise, can be traced to the same source; it is only very exceptionally, however, that a sinus passing into the neck from an internal pharyngeal orifice expands into an *aerocele*. *Godlee* and *Bucknill*, however, in recording such a case in 1901, referred to a comprehensive paper by *Kostanecki* in 1890 which, whilst dealing generally with lesions of branchial origin, such as cervical fistulae, sinuses, and cysts, mentioned a number of recorded cases in which an internally opening sinus had developed into a well marked diverticular *aerocele*, which presented as an obvious air-filled swelling in the neck.

*Watson* of Edinburgh recorded the first case of this form of diverticular *aerocele* in 1875; found in a dissecting-room subject, it reached the level of the clavicle and resembled a Florence flask with a very elongated neck, which opened by a small orifice at the favourite spot just behind the tonsil on the palato-pharyngeal fold.

The next record was also British. The elder *Wheeler* described and illustrated an enormous air-filled cervical diverticulum (*aerocele*); it was as large as a fair-sized orange. At operation it was found to extend in front of the sterno-mastoid, and was covered by a thin layer of muscle which I surmise was the platysma; it reached the

clavicle below and the middle line over the thyroid cartilage in front. The stalk was traced upwards between the two carotids, and entered the pharynx in a space bounded by the palato-pharyngeus and the stylo-pharyngeus laterally and the middle and superior constrictors above and below. This diverticulum, Wheeler states, could be traced to the right sinus pyriformis, and the opening was apparently large in contrast to that of the lesions described by Watson and by Godlee. After removing this sac Wheeler unexpectedly discovered another diverticulum lower down, originating posteriorly from the deep pharynx and passing down behind the oesophagus. This true pharyngeal pulsion diverticulum was the size of a walnut, and was removed. Wheeler had, therefore, in 1886, the distinction of being the first to operate on, and to remove successfully, a congenital lateral pharyngeal diverticulum with survival of the patient; though the latter procedure of excising a pulsion pouch had been previously (in 1884) performed by Niehans and von Burckhardt, but with a fatal result in each instance.

These diverticula, though more commonly having a small opening in the region of the posterior faucial pillar just behind the tonsil, may, as in Wheeler's case, open lower down; the neck in Godlee's case passed through the lateral part of the thyro-hyoid membrane, and in another instance the opening was large enough to admit a finger somewhere in the region of the glosso-epiglottic fossa. Although the records describe these sacs as containing air and some secretions, and in one instance grumous material, it would be imagined that, where the pharyngeal opening happens to be large, food must sometimes get in; but perhaps there is a valvular condition of the orifice which prevents this happening as a rule. Certain it is that the presence of food in the sacs is not mentioned in any of the records I have consulted; but I cannot claim that my search has been exhaustive.

#### HISTORICAL NOTES ON PULSION DIVERTICULA OF THE DEEP PHARYNX.

According to Zenker the first recorded case of such a pouch was made by an Englishman (Ludlow) in 1764, and the specimen, a large one which extended into the thorax, is preserved in the Hunterian Museum of the Royal College of Surgeons. Zenker and von Ziemssen give references to no fewer than twenty-two cases, in which the diagnosis was rendered unequivocal by *post-mortem* examination, which were recorded between 1746 and 1879, and they add five cases of their own in the same category. In this list are included four English cases—namely, Ludlow's mentioned above, and one by Sir Charles Bell in 1816, one by Worthington in 1846, and one by Ogle (which is in the St. George's Hospital Museum) in 1865. Zenker also refers to seven recorded cases, in which, however, there was no autopsy, including one described by Dendy in 1848 and another described in the *Edinburgh Medical Journal* in 1856.

I have already alluded to the important case reported by Wheeler of Dublin in 1886, which was of especial interest in that it was not only the first one cured by surgical removal by a lateral incision, but the case was complicated by, and operation was undertaken for the removal of, a very large congenital lateral post-faucial diverticulum of congenital embryonic branchial cleft origin. The lower pharyngeal diverticulum was unsuspected, and only discovered during the course of the operation, and of course it was removed at the same time as the large lateral air pouch.

The first description, in any way approaching accuracy, of diverticula in the region under discussion dates from a communication by Mondirre in 1833. In 1840 Rokitansky placed the subject on a sure basis. He it was who classified these pouches under two main headings—namely: (1) pulsion or pressure pouches, and (2) traction pouches. Although he devoted most attention to, and laid the foundation of our knowledge of, traction pouches of the middle region of the oesophagus, he showed remarkable perspicuity in pointing out that the pulsion pouches found high up really originated from the lower pharynx. Yet in spite of this clear statement, and the fact that the point was empha-

sized in 1887 by Zenker, these pulsion diverticula of Rokitansky, originating high up in the alimentary tract, have been almost habitually included under the heading of "Diseases of the oesophagus," and have been described as originating either at the extreme upper end of the gullet or else at the pharyngo-oesophageal junction, and the importance of Killian's dehiscence in the inferior constrictor, with hernia of the mucous membrane through the same, has been almost ignored even to the present day.

After Rokitansky, the next comprehensive and really illuminating account of diverticula of the pharynx and of the gullet was set forth with, on the whole, considerable accuracy by Zenker, writing independently in 1876, and also in collaboration with von Ziemssen in 1877, in the *Encyclopaedia of Medical Practice*, edited by the latter, the English edition of which appeared so far back as 1878. In volume viii of this work, under the section dealing with diseases of the oesophagus, they included, it is true, diverticula of the pharynx, for they write:

"In a careful investigation of the subject we must overstep the true limit of the oesophagus and consider also the lower portion of the pharynx at the same time, since some of these diverticula, strictly speaking, belong to the pharynx. . . . In the literature such pharyngeal diverticula are repeatedly and erroneously described as oesophageal."

This statement is surely sufficiently definite, yet even at the present day this erroneous nomenclature as regards these herniae of the pharynx is perpetuated in our textbooks, both general and special, and in the report of cases in current journals. Zenker, following Rokitansky, divided diverticula in the upper food tract into those resulting from (1) pulsion and (2) traction, and stated that the two forms "are so totally distinct and different that it is impossible by grouping them to give a general description of the disease. Although this has been done by nearly all writers, excepting—that is, pulsion—Heschl." Zenker thought that pressure—that is, pulsion—diverticula were limited to the true pharyngeal diverticula, corresponding to the true pharyngeal diverticula, and that traction diverticula were limited to the gullet. The latter statement is apparently true, but it is not a fact that pressure diverticula do not occur far remote from the pharynx—that is, unequivocally in the oesophagus, and mostly in the middle third, but exceptionally both high up and quite low down. In reference to pressure diverticula, however, they state later that "they are located, as it appears, exclusively (certainly only with rare exceptions) at the lowest part of the pharynx just at the upper boundary." Although it turns out they were here right in not postulating too absolutely that these pulsion pouches were limited to the pharynx, they were not strictly accurate in placing them "at the lowest part of the pharynx just at the upper boundary of the oesophagus," for the pouches really originate, as was first definitely shown by Killian, at the junction of the oblique and transverse fibres of the inferior constrictor (cricopharyngeus) muscle and at least a centimetre above, not "just at the upper boundary of the oesophagus." Zenker, however, fully realized that the pouch was, in many cases, surrounded at its neck only by "the transverse continuous fibres of the inferior constrictor muscle at all events," and further on in the article Zenker, in alluding to his dissections, disposed of the erroneous statement of others that the pouch has a muscular coat, more especially in the smaller sacs (Klebs); he and von Ziemssen assert this view to "be untenable when we consider the arrangement and origin of the fibres of the inferior constrictor through which the mucous coat passes."

In spite of this clear statement that these herniae of the lower pharynx pass through the fibres of the inferior constrictor, many writers (from Butlin in 1893 down to those of the present day—for example, Chevalier Jackson, Shallow, and the Mayo staff) have taught that they are at times situated at the junction of the pharynx and gullet, and imply that they are as much oesophageal as pharyngeal in origin in some instances. In my opinion they are wrong.

Others, again, have considered that some of these pouches originated definitely just below the lower margin of the pharynx and through the posterior wall of the

extreme upper end of the oesophagus, in the alleged Lannier-Hackerman weak area. Killian proved conclusively that there were no known museum specimens which supported this oft-quoted view. Killian also showed that the pouch in the early stages consisted, as held by Zenker and von Ziemssen, of the fibrous submucous and mucous coats only of the pharynx. The fact that muscular fibres are found round the neck of moderately advanced and larger specimens is, in my opinion, explained by the fact that the hernia, when it attains a large size, tugs on the margins of the separated oblique and transverse portions of the inferior constrictor, and thus enlarges the mouth of the sac by traction and pulls down some of the fibres around the neck.

As regards the statement that there is a weak triangle at the postero-superior aspect of the extreme upper end of the gullet, where the muscular fibres are stated to be either sparse or absent, this heresy owes its origin to Lannier and Hackerman, and has been repeated, on absolutely insufficient evidence, by many writers in textbooks and special articles. In 1910 Waggett and E. D. Davis made a number of examinations of excised gullets in the post-mortem room, and conducted pressure experiments, and found that there was little warrant for such an assertion; as a matter of curiosity I repeated these observations and confirmed them.

The long and short of the matter is that what are usually known as Zenker's pulsion diverticula are entirely pharyngeal in origin, and do not bulge through either the pharyngo-oesophageal junction or through the extreme upper segment of the gullet in the region of the Lannier-Hackerman triangle, and any nomenclature which suggests any origin other than through Killian's dehiscence—that is, between the two portions of the crico-pharyngeus—is not warranted. Amongst writers who have promulgated the erroneous views that some pressure pouches occur in this situation below the lower margin of the inferior constrictor are Morell Mackenzie, Butlin, Zesas, Knott, Halstead, Starek, Stetten, and the majority of British and foreign writers on the subject, down to contributions this year by Shallow and Chevalier Jackson. John Morley, like StClair Thomson in his authoritative *Handbook*, correctly describes these pouches in the text, but Morley, under the wrong title of diverticula of the oesophagus, and Thomson deals with them under the section devoted to oesophageal diseases. A recent notable exception deserves mention—namely, the paper on pharyngeal diverticula by Wilkie and Hartley in the *British Journal of Surgery* (1922), which is refreshingly free from the usual errors of fact and from misleading nomenclature.

#### DIAGNOSTIC SYMPTOMS AND SIGNS OF PHARYNGEAL PULSION POUCHES.

The classical symptoms recorded by Rokitsansky, and later by Zenker, well back in the last century, were so much to the point that they stand to-day. Dysphagia, intermittent in the early stages and very gradually getting worse and more constant after years; immediate regurgitation of food at times, as in other forms of stenosis of the pharynx and gullet, but associated also with slight regurgitation of portions of food long after a previous or a meal or even two before the last; variable discomfort in swallowing rather than any difficulty in getting down ample nourishment is the rule and this not merely in the early stages, so that extreme loss of flesh is most exceptional and slight loss not so frequent as might be expected, even when the pouch is of long standing; aphagia necessitating gastrostomy appears amongst the records of last century; gurgling noises due to the mingling of swallowed air with the food stagnating in the pouch; in advanced cases there may be an obvious, visible, and palpable swelling on one or other side of the neck, more usually the left; external pressure may lead to ejection of the contents when food is present in the pouch. Discomfort rarely amounting to actual pain may occur from temporary overdistension and imprisonment of ingesta in the sac. Pouch patients are also liable to get distressing fits of choking and coughing sometimes, becoming actually cyanosed when food ejected from the pouch finds its way out suddenly and overflows into the air passages. In a case described and illustrated

by Robinson of Sunderland the pouch extended upwards towards the base of the skull behind the middle and upper pharynx as well as a long distance downwards behind the gullet, and when the patient swallowed water the neck swelled out laterally like the pouter pigeon, and for a few minutes at times presented the appearance of goitre.

A stricture high up in the gullet may exceptionally bear a superficial resemblance in symptoms, for a time, to a pouch, but a definite diagnosis can always be made, when efficiently carried out in the correct position, by an x-ray examination in conjunction with barium or bismuth paste. It is often useful partially to fill the sac through a rubber tube with paste instead of allowing the patient to swallow it. The endoscopic findings are characteristic but rarely really necessary for diagnostic purposes alone. The orifice of the sac is easily seen through the endoscope, but the lumen in the deep pharynx leading to the mouth of the gullet is often difficult to find even by experts. It can, however, be located by the swallowing of a shotted string.

#### TREATMENT OF DEEP PHARYNGEAL PULSION POUCHES.

When Zenker wrote his articles in 1876 and 1877 the only treatment recommended when the condition of the patient approached aphagia, and when there was failure to insert easily a rubber or gum-elastic feeding tube through the prolapsed pharyngo-oesophageal orifice into the gullet, was the performance of gastrostomy. He and von Ziemssen wrote, however, as follows:

"The radical cure of diverticula by operative procedure from without is one of our vain wishes; yet we should hope that even this operation conducted on Lister's plan might at some future day be performed without danger."

This "vain wish," first suggested by Kungo in 1864, and then by Hamburger in 1871, and attempted, but not with survival of the patient, by Niehans in 1884, was first successfully realized by Wheeler of Dublin in 1886, when he encountered a deep pharyngeal pulsion pouch whilst removing an enormous congenital lateral pouch or aerocele, and he promptly excised both. Zesas and Niehans, von Bergman, Kocher, and Butlin repeated this operation between 1888 and 1892, and primary excision has remained the method of choice in the main ever since. A few operators—for example, Stetten—recommend a preliminary gastrostomy. This appears to me to be neither necessary nor even justifiable; at all events my seven cases were successful without it.

Primary excision of the pouch through a cervical incision along the anterior border of the left sterno-mastoid and dissecting down to the side of the pharynx and gullet, severing the omo-hyoid muscle, tying the superior thyroid vessels, and displacing the left lobe of the thyroid gland, is a comparatively easy procedure, and has been described in detail by Butlin and others. Operation should always be preceded by what the earlier operators called the "toilet of the pouch"—namely, washing it out clean with some mild antiseptic beforehand. A bougie in the sac and another in the gullet considerably helps to define these structures and aids in the subsequent separation of the pouch by blunt dissection. If a bougie does not pass readily into the gullet beforehand, it can easily be manipulated into it when the deep preliminary dissection to the region of the side of the gullet is made. When the pouch has been freed from its bed considerable difference of opinion prevails as to the method of cutting through the neck close to Killian's area of dehiscence. I think, however, that simple incision is sufficient, though some operators still prefer to ligature the neck first, and divide it distally with the electric cautery knife.

The crux of the whole operation depends largely on the method of sewing up the orifice left when the pouch has been removed. Formerly the mucosa was invaginated and the fibrous coat sewn up by Lembert's method of suture. At the present day, however, most operators resort to some form of purse-string suture. The method of Wilkie and Hartley will be alluded to later. John Morley advocates the technique adopted in closing a duodenal stump in a Polya gastrectomy, and considers that excision of a pulsion diverticulum "should only be attempted by those who have

served a long apprenticeship to the technique of gastro-intestinal surgery." It would be thought that familiarity with the surgical anatomy and experience in surgical operations in this region of the neck were rather essential to operative confidence and success, and that one need not be an abdominal surgeon to carry out any method of suture for closure of the hiatus, in the lower pharynx, left after excision of the diverticulum.

Several alternatives to simple primary excision have been either advocated merely or else actually carried out. The former include painting the interior of the sac with silver nitrate (Dendy); dissecting out the sac free from its bed by a lateral incision, and then invaginating it into the food tract (Girard); the orifice being stitched up posteriorly to endeavour to prevent recurrence to the original position, which, however, has occurred sooner or later in several cases, and the method has fallen into disfavour on that account. Another method advocated, but not carried out, was that of Chevalier Jackson, of passing a volsella through the endoscope down to the interior surface of the fundus and endeavouring to perform internal traction invagination into the pharynx without making an external cervical approach. As I remarked in reviewing Jackson's larger work twelve years ago, the suggestion showed that he had no experience of dissecting out a pouch free of its adhesions, or he would have known that the latter would not yield to internal traction.

Statistics compiled by Stetten in 1910 showed that there was a mortality of no less than seven in the first thirty recorded cases of simple primary excision alone, though carried out by first-rate general surgeons for the most part. This high mortality of over 23 per cent. would probably have been greatly exceeded if he could have got at the number of unrecorded fatal cases. It is, however, significant that there were only two deaths in the next eighteen recorded cases, and, on the other hand, Stetten found that of five other cases, in which primary excision was preceded by gastrostomy, there was only one death, and that was avoidable probably, because obviously due to very injudicious after-treatment. Stetten recommends this preliminary measure which he himself followed, but I regard it as only exceptionally justifiable.

It was probably the high mortality that led up to the Goldmann operation of removing the pouch in two stages.

The two-stage excision is generally credited with having been first successfully carried out by Goldmann in 1907, but Halstead, in his article in *Surgical Clinics of Chicago* in 1919, claims that he first practised it, though he gives no reference to priority of publication over Goldmann, who recorded two successful cases in 1907. It does not appear to have been performed very frequently on the whole, though some operators prefer it in all cases, but others especially reserve it for very large pulsion pouches (Colledge).

The first stage of Goldmann's operation consisted of freeing the pouch from its bed by an incision along the anterior border of the sterno-mastoid and subsequent dissection as in the operation for the primary excision; instead, however, of cutting off the pouch at its neck, it was turned up with the fundus above, and the latter was stitched up to the upper angle of the operation field, the neck was lightly constricted with catgut, and the skin incision was then sewn up except at its lower end. Ten or more days afterwards, when the cervical lymphatics were presumed to have been sealed and the risks of mediastinal infection reduced, should subsequent leakage occur, the wound was reopened, the pouch excised, the neck suitably sutured, and closed as in the operation of simple primary excision.

Subsequently Goldmann tried a modification of this method: the pouch having been dissected free, a catgut

was tightly—not lightly as in the first method—tied round the neck of the pouch so as to ensure strangulation and necrosis of the pouch, which was packed up with gauze high up in the wound; the skin incision was only partially sewn up, being left open at the upper as well as at the lower end. The second stage consisted in removing the pouch when it had separated at its neck by sloughing a week or two later. This, of course, meant leakage. It was a dirty procedure and proved not to be free from risk, though Marsik and others adopted it for a time. When the Goldmann two-stage method is mentioned to-day it is the first type which is usually referred to.

Wilkie and Hartley modified the first Goldmann operation, which they prefer to primary excision, by incising the pouch and performing a submucous resection of the mucosa, which they remove, leaving the fibrous coat, which they then invaginate and sew up by purse-string sutures.

Bevan's method of obliterating the cavity of the pouch without excision, in order to reduce the risk of leakage, is theoretically ingenious. The sac having been dissected out free from its bed under local anaesthesia, Bevan proceeds, if the pouch is of moderate size, not more than 2 inches long, "to invaginate with three purse-string sutures of black silk or Pagenstecher linen one-half of the diverticulum into the other half, then the rest of the diverticulum should be obliterated by longitudinal sutures, six or eight, running parallel with the long axis of the diverticulum." When the operation is completed the area of the mouth of the pouch at Killian's dehiscence presents as a firm rounded button or knob on the posterior surface of the lower pharynx. In dealing with a large long diverticulum another method is employed by Bevan.

"The diverticulum can be crushed at its centre with a pair of heavy forceps, tied with a silk ligature, and the portion distant to the ligature cut off with the electric cautery. The remains of the diverticulum which are then no larger than one's thumb can be treated by invaginating them into the oesophagus" (meaning pharynx) "with three purse-strings just as we handle the smaller diverticula."

The patient is fed by a feeding tube passed for each meal for ten days.

Bevan does not allude to any cases in which these operations have been

carried out, so we know nothing as to whether they were successful for a time, or whether there was any recurrence of symptoms, as occurs sometimes after Girard's invagination; nor is anything said about subsequent leakage ever having happened. The latter would appear to be not unlikely in any but a pouch with an extremely thick wall instead of the usual thin wall; and considering that from nine to eleven sutures are inserted it seems extremely likely that the wall would be perforated, and possibly leakage and sepsis result. In the significant absence of any statistical record of the cases operated on and the immediate and remote results, judgement must be suspended as to the value or otherwise of Bevan's really ingenious proposals.

My operation of upward suspension and fixation of the freed and inverted pouch was described under the name of "diverticulopexy" in connexion with a case in which I carried out this operation, shown at the Laryngological Section of the Royal Society of Medicine in 1917 and recorded in the *Proceedings* in 1918. It consists essentially of the first stage of the Goldmann operation. The pouch having been freed from its bed by dissection and isolated is then turned down-side up and the fundus stitched up as high as possible to the upper angle of the operative field by sutures to the side of the pharynx and to the deep cervical fascia under the sterno-mastoid. In order that stitches shall not perforate the sac wall and shall hold it, it is essential not to make a clean dissection of the sac, but to leave as much areolar tissue as possible adherent to

FIG. 1.—Typical posterior pharyngeal pulsion diverticulum showing the marked prolapse of Killian's lip.

its wall; before stitching the pouch up I pass a catgut ligature around the neck of the sac, but do not draw it sufficiently tightly to produce strangulation. The object of this is to prevent food entering the pouch in the first weeks following operation.

For a very large intrathoracic pouch, really too long for successful suspension, it might be advisable to do the second stage of the Goldmann operation if a radiographic examination showed that the pouch was inclined to prolapse after a short period. I do not recommend the operation for a small walnut-sized pouch, as in the only case in which I did a "pexy" in such circumstances the symptoms recurred from prolapse a year later, and I then resorted to excision. The method, therefore, is probably liable to fail in extremely long pouches extending well down into the chest, and also in rather small pouches. In addition to the case of the small pouch which recurred, I have done four other cases of suspension, with complete relief in each up to the present—that is, for five years or more. I also assisted Sir James Dundas-Grant in dealing with a rather long pouch by this method. There is, of course, no chance of leakage if the wall of the sac has not been perforated by suture and the dreaded mediastinitis is eliminated.

The cause of dysphagia in these diverticular cases is not, as is usually held, so much due to pressure on the oesophagus from behind by food in the pouch, as to prolapse or downward displacement of Killian's lip, which forms the lower border of the mouth of the pouch; this prolapse displaces the plane of the pharyngo-oesophageal junction from a horizontal into a more or less vertical plane, and prevents the normal opening up of the mouth of the gullet during deglutition. The suspension and fixation upwards of the pouch corrects this marked prolapse and draws up Killian's lip together with the posterior wall of the cervical gullet, into its normal position, and the patients are able to swallow normally the same evening in most instances. The prolapse of Killian's lip is well shown in museum specimens, but the point has not, I think, been previously emphasized.

Morley states that I and König advise suspension by suturing the sac to the hyoid bone or to the omo-hyoid muscle; that is the method described in 1922 by König, but has not been hitherto carried out by me. It may be worth while to use these points as additional attachments for the pouch.

Of course, the tendency of most "pexies" is to recur, but this only happened to me in the one instance of the small pouch above mentioned.

#### TRUE DIVERTICULA OF THE OESOPHAGUS: THEIR ETIOLOGY, SYMPTOMS, AND TREATMENT.

Very few pouches in the gullet have been recorded other than the traction diverticula of Rokitsansky behind the roots of the lungs; whether these latter are as prevalent as he asserted, though latent, and whether they are so often as he believed, the determining factor in serious lung and pleural abscesses and in mediastinitis, when decaying food is retained, is still a moot point.

Traction diverticula are usually unsuspected till found at necropsies; their cause is, on the other hand, evident, as they can always be traced to a previous breaking down of a suppurating lymph gland which forms an inflammatory adhesion to the outside of the wall of the gullet, which gets dragged out of position by subsequent healing and cicatricial contraction. They are rarely observed at any spot other than in the middle third of the gullet behind the area of the glands in relation to the bronchi and trachea. Jackson has, however, recorded a traction diverticulum of the supraclavicular gullet, and they have also been observed low down near the diaphragm, presumably from the adhesion of breaking down mediastinal glands. Traction pouches, which are normally narrow

funnels, may very exceptionally become greatly expanded by food lodging in them, and when this stagnation ectasia happens we have the traction-pulsion diverticula of Starck.

The rare true pulsion diverticula of the gullet, which occur usually in the lower half, though occasionally higher up, may sometimes be due to increased deglutitory pressure when there is either a benign inflammatory or a functional stricture of the gullet, as suggested by Hurst, but this would hardly apply to such pouches higher up, or where there is no obvious stricture. When pressure pouches are associated with and result from functional or from cicatricial stricture at the level of the diaphragm the treatment is obviously that of relieving the causal obstruction. Pouches which have no underlying stricture in the gullet, excepting Leugart's variety, do not themselves appear to have often any recognizable symptoms; they are at times accidentally discovered either at necropsy or when making radiographic or oesophagoscopy investigations, and there is no *ad hoc* surgical or other treatment either necessary or even possible beyond, perhaps, lavage.

Leugart's pouching is extremely rare. I have only seen one well marked example—namely, in a case I was asked to examine with Atkinson at the Central Throat and Ear

Hospital. In this case there was a well marked lateral recess in association with a prominent horizontal ledge projecting internally from the anterior and left lateral wall of the gullet at the level of the left bronchus. Both Leugart himself and Halstead thought that the gullet was actually compressed by the left bronchus itself in these cases; this is obviously wrong, as the ledge passes backwards and to the left, which is not in any way the direction of the left bronchus, of course, and the latter never comes directly in relation with the wall of the oesophagus. I think the probable explanation is that contracting connective tissue bands pass from the bronchus outwards and backwards to the left side of the body of that dorsal vertebra which lies behind the gullet at the level of the left bronchus. I have on many occasions when making an endoscopic examination observed a slight ledge in this position, and it is so frequent as to have been alluded to as marking the

site of the alleged bronchial constriction of the gullet. The enlargement of this not uncommon, though usually slight, ledge so as to intercept large, fairly undivided portions of ingesta—for example, large portions of potato—is very rarely observed, but in time a recess may form in which solid portions of food get arrested, pouching follows, and slight dysphagia is observed; at least, that is what apparently happened in Atkinson's patient. Here, again, cutting endo-oesophageal surgery is not advisable, but the passage of large bougies might possibly be useful, or else stretching by Brüning's dilator.

To render this review comprehensive I must not omit to mention that a dissecting diverticulum has been recorded passing down between the coats of the gullet. This condition probably resulted from ulceration down to the muscular coat, and subsequent separation of the coats by pulsion.

Another rare form is a narrow diverticular sinus of varying length and unknown origin, though traumatism, or ulceration, may be suspected. I had an instance of this lesion an inch and a half long, which passed backwards, downwards, and outwards near to and parallel with the diaphragm, *post mortem* in a case of phreno-cardiac stenosis.

To sum up: diverticula of the gullet, in contrast to diverticula in the pharynx, are rarely suspected during life, rarely cause obvious symptoms, and are rarely susceptible of or influenced by any treatment, even should they accidentally be discovered during life. We hear very little of them, and for the above very obvious reasons.

## LARGE PHARYNGEAL DIVERTICULA.

BY

E. I. SPRIGGS, M.D., F.R.C.P.,

Senior Physician, Ruthin Castle, North Wales.

The following details relate to two patients with large pharyngeal pouches of long standing which had not been operated upon. The first had been present for over forty years.

#### CASE I.

The patient was a man, aged 76, who sought admission to Ruthin Castle early in 1924, for an affection of one hip-joint, stating that he was otherwise in good health. When giving his history he said that a pressure pouch of the oesophagus had been diagnosed by Sir (then Mr.) Henry Butlin, thirty-eight years before. He had managed the pouch for the whole of this time, the only serious disadvantage being that occasionally at a meal it might discharge involuntarily through the nose. This accident was rare and often did not occur for several months, but the fear of it is present when he is obliged to dine in public rooms in hotels or on a ship. He had lived a very active life, travelling, riding to hounds, and walking long distances, even recently as much as twenty-five miles a day.

With a barium meal a large pouch of clear outline can be seen extending into the thorax as low as the fourth vertebra and below the level of the aortic arch (Fig. 1). It is a little more to the right side than the left.

The procedure which the patient has evolved for managing the pouch is as follows: he retires after each meal, bends forward and makes an effort to increase intrathoracic pressure, putting the closed hand, the back of the first phalanges, against the left side of the neck above the clavicle, and ejects part of the contents of the pouch through the mouth. He then takes a glass of water, evacuates again, and is comfortable and safe from disturbance.

Since the lower part of the pouch is not mainly on the left, it appears that the placing of the back of the hand on that side probably supports the upper part of the pouch or protects a weak place, and this aids in raising thoracic pressure without discomfort. When this procedure was carried out with a barium and buttermilk meal, the first evacuation got rid of three-quarters to four-fifths of the contents of the diverticulum (Fig. 2).

With subsequent meals the glass of water was taken as usual, but some barium returned at the end of the day. The patient believes, however, that with ordinary food there is complete emptying after each meal. In a recent letter to my colleague Dr. Anderson this patient states, for the benefit of anyone in a similar plight, the result of his forty years' experience as follows:

1. All food left in the pouch must be expelled within a few minutes after a meal and the throat gargled with cold water.
2. The saliva should be expelled also before getting into bed.
3. Alcohol must be regarded as a poison; "I allow myself one glass of Madeira to my dinner, however."
4. Beef should be avoided unless minced.
5. Devonshire cream is recommended as a good lubricant which is well borne.

#### CASE II.

In this patient, a man aged 70, also not operated upon, the symptoms dated back sixteen years. It was first noticed that food began to be arrested on swallowing, and that a piece of meat would return. Twelve years later—that is, four years ago—the symptoms became worse and weight was lost. At the time of the first consultation, twenty months ago, he could take only soft food, mainly cereal, with milk, milk pudding, butter, bacon fat, and some fruit pulp. Food tended to come back and had to be swallowed again or rejected. Fits of choking occurred, when food might return through the nose. The pouch could be emptied voluntarily. On one occasion this was done in my presence. About half a pint of brown fluid was produced, with the odour of coffee; some fat was floating on the surface. The fluid was acid to litmus, but contained no free acid.

On x-ray examination with a barium meal a large pouch was seen which, in an antero-posterior view, extended into the thorax well beneath the level of the clavicles as low as the fourth dorsal vertebra, most of it being to the right side of the middle line. It was irregular in outline. In the lateral view it can be seen to come below the level of the aortic arch. The mouth of the diverticulum appeared to arise from the posterior part of the pharynx just above the junction of the gullet. It was found on the x-ray table that food passed into the oesophagus more easily in the prone position (Figs. 3, 4, and 5).

This patient was recommended to take food lying forward on the right side. A year later he was holding his own; the weight was the same and he had little discomfort. He found it better not to empty the pouch during the day, as if it were kept full food would pass over it into the stomach. It was then emptied each evening after the last meal.

These were regarded as pressure pouches. Such diverticula have been called congenital, just as have the diverticula arising from the second part of the duodenum, and with no more evidence. They both arise in adult life at a part of the alimentary tube where there are frequent rises of pressure from the contraction of the muscular tube above and where the tube is weak from the divergence of muscular fibres. There may be a sphincteric contraction below, as described by Wilkie and Hartley.<sup>1</sup> When the pharyngeal pouch is once formed we may add to these factors a definite obstruction below; for the neck of the filled pouch will pull upon the gullet at its origin (Fig. 5, lateral view). During swallowing the lower part of the pharynx then becomes a closed cavity, the pressure in which will distend the diverticulum more and more.

In neither case was there any unpleasantness or putrefaction in the contents of the pouch.

Both of these men would be much better off had the pouch been successfully removed. In the first case operation was refused by the patient many years ago. His last consultation with Mr. Butlin was about 1893. At that time he was told that the mortality of the operation was about 50 per cent. It must be admitted that he has done well by his own methods. He does not suffer, casual acquaintances have no idea of the disability, and he has lived, and still lives, an active interesting life.

In the second case failure of nutrition set in definitely four years ago, but on considering the patient's age and physique, two surgeons advised independently against operation. By experiment and observation, including the finding out in the x-ray room in what position food entered the oesophagus most easily, the patient (who is a retired medical man) and his advisers have evolved simple means of diet and living which have enabled him to hold his own.

The photographs shown are by Mr. O. A. Marxer.

#### DISCUSSION.

Dr. Irwin Moore (London) agreed with Dr. William Hill that such diverticula should not be described as oesophageal. The site at which a pressure pouch originated was in every case so definite and constant—namely, the posterior wall of the deep pharynx, between the oblique and transverse fibres of the crico-pharyngeus muscle—that there was no reason whatever why such pouches should be described as other than pharyngeal. Again, frequent endoscopic examinations had confirmed the fact that the slit-like opening of the lower pharyngeal orifice was always situated at a slightly lower level than the mouth of the pouch, which was definite proof that such pouches were pharyngeal in origin. Their lateral relationship to the oesophagus was probably the reason why they were frequently and erroneously described as oesophageal.

Dr. Irwin Moore pointed out that Dr. Hill had omitted to include in his classification acute diverticula, which were, however, very rare. Hoffmann in 1899 had recorded such a condition in a man, aged 31, who died after accidentally swallowing a piece of china. At necropsy an opening was found in the "upper region of the oesophagus" (? deep pharynx) which was lined with mucous membrane. Again, Dr. Hill had not mentioned artificial pouches, produced by habitual criminals in India for the purpose of concealing stolen money. A specimen in the museum of St. Bartholomew's Hospital, removed after death from a convict, who had made a pouch in his throat for keeping money, showed a pouch formed by the prolongation downwards of the left sinus pyriformis. Lead weights, varying in weight from 12 to 70 grains, were used to increase the depth of the sinus pyriformis. These discs were attached by a piece of string to one of the teeth to prevent them from being swallowed. Criminals with coins secreted in these artificial pouches might be inverted and shaken without the coins coming away. Dr. Irwin Moore also pointed out that under the heading of "congenital lateral pharyngeal aerocoeles of abnormal branchial cleft origin" Dr. Hill had included the case recorded as a "pharyngeal pouch" by Godlee and Bucknall, in 1901. This case appeared, however, to have been wrongly described by them, for it was undoubtedly a "laryngocoele," since the sac contained air and its origin was laryngeal. The late Professor Shattock was of the opinion that, etymologically, the term "pneumatocoele" would be a better term than "aerocoele" in cases where it was thought desirable to indicate the fact that the sac contained air and not fluid. In a paper published in 1922 on "The so-called prolapse of the laryngeal ventricle and eversion of the sacculus laryngis" Dr. Irwin Moore had specially investigated this case with the help of Professor Shattock, and had come to the conclusion that there were no grounds for describing the tumour as a pharyngeal pouch. Professor Shattock also stated that, at the time the case was published, Professor Arthur Keith had expressed the opinion that it was an enlarged air sac. When first seen by Rickman Godlee and Bucknall the tumour looked like an enlarged thyroid gland on the left side of the neck at the level of the hyoid bone, and in front of the sterno-mastoid muscle. It was soft and tympanic on percussion, freely movable over the deeper parts, except at the top of the larynx, to which it was fixed, and the movements of which it followed during deglutition. Pressure caused diminution in size. When seen six months later the tumour had reached the middle line of the neck, and extended to the posterior border of the sterno-mastoid muscle up to the angle of the jaw and down to the clavicle. Not only did it give a tympanic note on percussion, but, on holding the breath and blowing, the patient could slightly inflate the tumour, producing a change in the percussion note. At operation the pedicle, which was secured and ligatured outside the larynx, passed through the thyro-hyoid membrane, and careful probing failed to discover an actual communication with the pharynx. This case therefore came obviously under the group of "laryngocoeles"—a term introduced by Virchow in 1867 to describe those cases of thin-walled air sacs which arise in connexion with the laryngeal ventricle (pneumatocoele of the sacculus laryngis).

Dr. Irwin Moore next referred to the etiology of pharyngeal pouches. Two hypotheses had been put forward: (1) that they were congenital, but no evidence had been submitted which supported this view; (2) failure of the circular muscle fibres of the crico-pharyngeus to relax in the process of deglutition—in other words, a spasm of the lower sphincter orifice of the pharynx, followed by arrest of the bolus of food and dilatation of the hypopharynx, giving rise to increase of intrapharyngeal tension, the upper portion of the inferior constrictor acting as a force-pump, and causing the mucosa to bulge at the part where there was admittedly the least muscular support. Pressure of the pouch when filled with fluid or food helped to increase the difficulty of swallowing and to increase the size of the pouch.

There was no question that the thinness of the wall of the gullet as a whole—in this position—was very marked as compared with its thicker walls lower down. In the

speaker's opinion the latter view of the formation of these pouches was the correct one. The majority of these pouches had a narrow mouth and neck, the mouth averaging one inch in diameter. The relationship of the orifice of the pouch to the lower sphincter orifice of the pharynx was well shown in a view from above in a specimen in the museum of St. George's Hospital.

To illustrate further the position and formation of retraction pouches of the oesophagus Dr. Irwin Moore showed a drawing of a specimen in the museum of University College Hospital, to which the following description was attached:

"The pouch is in the anterior wall of the oesophagus, 3 cm. below the bifurcation of the trachea. It is of small size and its opening about 1 cm. in diameter. The interior is lined with normal mucous membrane. In the bifurcation of the trachea is a group of pigmented and calcareous glands, and to the lowest gland is adherent the apex of the conical protrusion of the muscular wall of the oesophagus which forms the pouch. From a man who died in University College Hospital of pulmonary tuberculosis."

With regard to the treatment of pharyngeal pouches, Dr. Hill had only dealt with the surgical and not with the medical treatment of these cases. Many surgeons had declared that only extirpation or other operative procedures could be recommended, and that without operation the case must inevitably go from bad to worse until starvation, sepsis in the neck, mediastinal abscess, or septic pneumonia ensued. Among a number of cases which had been through his hands there were two, which he had recorded, in which no operation had been performed, and it was interesting to note their later history.

#### CASE I.

The first patient, a lady aged 64, had consulted him, at the advice of Dr. Lewarne, Cricklade, in August, 1912. From her symptoms it was thought that she was suffering from malignant stricture of the oesophagus. She had been weakly since childhood, and for four years she had had difficulty in swallowing any dry food unless it was first moistened and softened. Tough or stringy meat had to be taken with gravy. All foods, and even liquids, had to be swallowed very carefully, slowly, and in small quantity, otherwise they caused irritation, coughing attacks, and regurgitation. She expectorated a considerable quantity of mucus, especially at night. Her weight was 10 st. 2 lb.

This case was first diagnosed under cocaine anaesthesia by the oesophagoscope. In passing through the cricoid pharynx the tube entered a cavity posteriorly, with its walls lying in folds, coated with stale-smelling slime. The further progress of the tube was abruptly stopped, and no outlet could be found. On withdrawing the tube the slit-like opening of the lower pharyngeal orifice was seen anteriorly and at a lower level. The tube could be passed with great ease in and out of the posterior aperture, but could not be passed into the oesophagus. The diagnosis of a pouch was confirmed later by x rays and a bismuth meal, the swallowing of which was carefully watched. It was observed that the bismuth at first passed quickly out of the mouth for a short distance, then was suddenly held up. As more bismuth was swallowed the outline of the diverticulum became gradually depicted in the neck—situated almost centrally in the middle line. The upper border appeared to be situated at the level of the cricoid cartilage, and the lower extending downwards for 1½ to 2 in. As the pouch became overfilled and stretched with the bismuth a portion of the latter was seen to well over the top of the sac into the oesophagus, where it was momentarily delayed before descending slowly, but without further arrest, into the stomach. This phenomenon occurred with every fresh mouthful of bismuth swallowed, and suggested that the walls of the pouch were contractile, but further investigation proved that the patient emptied the pouch by contracting the muscles of the neck.

This patient was advised to live on soft food, to eat very slowly, and have the pouch washed out occasionally. In 1913 Dr. Lewarne reported that he could not persuade her to have the washing done, and that her present condition was no worse, and he had heard no further complaints. The patient herself reported, in 1915, that her throat was "certainly much better," and she swallowed with greater ease and comfort, though there was still some expectoration at night. In 1917 she wrote that her throat was much better, she could feed very well, though occasionally, with anything irritating, she had a "little choke." Her weight and general health kept up to the normal. Dr. Lewarne also wrote: "She has been wonderfully well without any treatment." On July 9th this year Dr. Lewarne wrote: "She is now 78 years of age, and going strong, and is quite active and able to get about. She still makes extraordinary noises during and after meals, but being very deaf these do not worry her."

#### CASE II.

The second patient, a lady aged 78, was first seen in June, 1916, recommended by Dr. Soltan Fenwick. She complained that while lunching in May, 1915, she suddenly had a choking feeling and swelling in the throat, followed by regurgitation of a small quantity of food. This occurred on two or three occasions during the year. Food had occasionally stuck "against a ledge" at the level of the sternal notch, and then had been regurgitated. There had been no trouble with liquid foods. She had suffered from

indigestion and constipation for years. This case was not examined endoscopically at the advice and wish of her physician, but was diagnosed by x rays.

Treatment for this patient's indigestion was prescribed and she was recommended to live on soft foods, also to swallow her food slowly and in small quantities.

In October, 1916, the patient wrote that her swallowing was no worse, though the "catching of food" was just the same. She was taking ordinary food, but had to eat and swallow very carefully or food might stick. There was no regurgitation of food. She had noises during swallowing, but mostly when lying down. She not only looked but felt very well. Dr. Soltan Tenwick wrote on July 2nd of this year that he had not seen her since 1916, but that he had heard that the symptoms had not increased. This patient is now 88 years of age.

These two cases showed that attention to feeding and digestion might be all that was required in some cases to improve the distressing symptoms caused by pharyngeal pouches and to prolong life, and that operative procedures might not be necessary in a number of cases.

Dr. Irwin Moore expressed the opinion—judging from the appearance of the x rays—that the case of a large pharyngeal pouch exhibited by Mr. Bell Tawse at the previous day's clinical meeting might be similar to an unusual specimen of a pharynx which he had come across in the museum of University College Hospital, and had been removed *post mortem* from a patient, aged 76, who had been under the care of Sir Rickman Godlee, and who died from bronchitis and pneumonia. To the lower extremity of this pharynx a pouch was attached measuring vertically 2 inches and from side to side 2½ inches. The speaker was struck with the unusual appearance of the pouch in this specimen, which had not been well dissected, and obtained permission from Mr. Lawrence to investigate the specimen with Professor Shattock, who carefully dissected the sac and bisected the specimen.\* In this specimen the pouch, which was particularly capacious, was unusual in that it rose as high as the upper level of the cricoid plate, and had a mouth of exceptional size. Like the summit of the pouch, the upper edge of its mouth lay at the same level; the sac involved much of the lateral as well as the posterior walls of the pharynx.

Dr. Irwin Moore considered that in Mr. Tawse's case a careful endoscopic examination with a medium-sized oesophageal tube which could be orientated would decide the actual size of the pouch opening and settle the question of operation. Again, a full lateral x-ray photograph would also help to decide the size of the pouch mouth, for in this position a much more accurate picture was obtained than in the anterior, antero-lateral, or posterior position.

The danger of an oesophagoscopy examination, or of dilating an oesophageal stricture co-existing with a pharyngeal pouch, should not be overlooked in these cases, for the oesophagoscopy tube invariably entered the pouch, and considerable difficulty might be experienced in finding the slit-like oesophageal lumen. If the mucous wall of the pouch was very thin, as might be the case, it was extremely easy to perforate the sac with the tube. This risk was well shown in the case of a male patient, aged 71, who died from mediastinitis forty-eight hours after the endoscopic passage of a bougie for a supposed co-existing oesophageal stricture; the bougie perforated the sac wall. When this patient was first examined by x rays with a bismuth feed, the bismuth was seen, in the first instance, to enter the oesophagus with difficulty—that is, a spasm occurred at the sphincter opening—and very little food passed down the oesophagus. After a few seconds the rounded shadow of the pouch could be clearly seen. When this had fully filled up, the passage of the bismuth down the oesophagus appeared to be facilitated, and the spasmodic movements observed at the commencement of the examination ceased. The bismuth remained in the pouch during the whole of the examination—from the commencement to the time the plates were taken—occupying about half an hour. The x-ray pictures were taken in two positions—namely, antero-posterior and left antero-lateral oblique. In the latter position there appeared to be a constriction at the entrance to the pouch. There was a distinct gap in the bismuth shadow below the pouch, then a fairly wide shadow continuing down for about an inch. A slight constriction at

this point gave the impression that there might be a narrowing of the lumen, hence the suggestion of a possible stricture of the oesophagus below the pouch. At necropsy the wall of the pouch was found to be so thin that it seemed surprising that spontaneous rupture had not previously taken place. The diameter of the oesophagus was found to be so reduced that it would only admit the little finger; it measured 14 mm. (nine-sixteenths of an inch). Dr. Irwin Moore considered this case of great interest in supporting the view that the predisposing cause and starting of a pharyngeal pouch was a spasmodic contracture of the crico-pharyngeus muscle.

Mr. LIONEL COLLEDGE (London) said he bore a message from Sir StClair Thomson, who regretted that he was prevented from attending the meeting by an attack of gout. Sir StClair had received a courteous rebuke from Dr. William Hill for including "pouches" under "diseases of the oesophagus" in the new edition of his textbook. Sir StClair was well aware of the pathological anatomy of the condition, but declined to be bound by any particular method of classification. The symptoms were oesophageal, and in a book which was essentially clinical in its outlook he preferred, after careful consideration, to rely on a clinical rather than on a pathological classification, which might even savour of pedantry in such circumstances.

Mr. KELSON (London) described the treatment of two cases by excision without subsequent leakage. One patient lived for four years and died of bronchitis; the other lived for a longer period and died of malignant disease.

Mr. E. D. D. DAVIS (London) said that the pathology of the propulsion pouch was similar to that of hernia, and was related to the weakness of the pharyngeal wall between the fibres of the inferior constrictor. Mr. Waggett considered that the increased pressure was due to swallowing and inco-ordination of swallowing with a spasm of the crico-pharyngeus muscle; most of these patients gave a history of dysphagia of long duration. The treatment was that of the radical cure for hernia. In any type of operation the weakness of the pharyngeal wall must be strengthened. In excision recurrence had followed in several cases, and after excision the wound in the pharynx should be carefully sealed and the sterno-mastoid pulled over and stitched over the opening. Diverticulopexy had failed in some cases, and in one case the pouch sloughed and a fistula resulted. Girard's or Bevan's method of inversion had also failed and recurrence ensued.

The PRESIDENT (Dr. Brown Kelly, Glasgow) referred to the symptoms of saliva in the throat and a gurgling noise on swallowing being useful in diagnosis. It was important to remember that operation was undertaken on account of serious symptoms such as dysphagia and loss of weight, rather than for the purpose of removing the pouch *per se*. Some patients possessing pouches consumed all manner of food and reported no loss in weight. He had been rather surprised that Dr. Hill did not pay more attention to endoscopic diagnosis than to x rays.

Dr. HILL, in reply to a question by the President, whether primary excision was to be considered as the operation of choice, said that in his historical review of operative methods down to 1892 he had stated that primary excision had remained in the main the method of choice ever since. He had in view the point that it was the choice of the majority of operators. Personally he preferred fixation suspension in suitable cases. Comment had also been made on the fact that no stress had been laid on endoscopy as a diagnostic method. Dr. Hill's view was that the diagnosis could be confirmed by endoscopy, but it might be dispensed with in all but doubtful cases, since a survey of the classical symptoms confirmed by radiographic findings was absolutely definite for purposes of diagnosis in most cases. The suggestion of Keith, mentioned by Dr. Irwin Moore, that "pneumatocoele" was a preferable term to "aerocele," he was prepared to accept, but he could not agree with the suggestion of Dr. Moore, following Sir Arthur Keith, that the pneumatocoele recorded by Godlee and Bucknill was a

\*By arrangement with Mr. Lawrence one half of the specimen was returned to the museum of University College Hospital, while the other half was included in the museum of the Royal College of Surgeons.

laryngocele; the neck had been traced through the thyroid membrane, and therefore it must be outside the larynx, and, of course, a pharyngocele, to which group Godlee rightly assigned it. Mention had been made of his omission to include the artificial enlargement of the pyriform fossa with the aid of leaden discs by natives of India and South Africa for depositing stolen coins and precious stones; he had been dealing exclusively with hernias and diverticular sinuses, not with mere artificial enlargements of natural cavities—with pouches, not with pouchings—and therefore had rightly excluded from illustration and consideration the interesting specimen in St. Bartholomew's museum.

## THE SORROWS OF THE SEPTUM.

BY

W. JOBSON HORNE, M.D.,

Surgeon to the Ear, Nose and Throat Hospital, Fitzroy Square, London.

THE text of this article is taken from Pliny's *Historia Naturalis* (Bk. XI, Chap. 91): "Man is the only creature from which the blood flows at the nostrils; some persons bleed at one nostril only, some at both."

Pliny made that observation nearly nineteen centuries ago. It is so simple. It is so true. It is, as I shall show, the *fons et origo* of all the sorrows of the septum.

There is no hæmorrhage of greater frequency, and no hæmorrhage that is sooner forgotten. For the latter reason I found it difficult when I wrote the article "Epistaxis" more than a quarter of a century ago for the *Encyclopædia Medica* to obtain very accurate statistics of its frequency. At that time I had the opportunity of putting questions to many hundreds of patients of both sexes, of all ages, and in all conditions of health. I found that one hundred and forty-two people in a thousand had recollection of the blood dropping from the nose. For the reason stated that must be accepted as a low estimate.

I further found that epistaxis was of more frequent occurrence in the male sex. Here let me anticipate by reminding you that deformities of the nasal septum are more frequent in males than in females. We now know—and this Pliny did not tell us—that the bleeding point in the vast majority of cases is to be found in the cartilaginous septum at a spot where there is a very free anastomosis of the terminal twigs of the vessels supplying the septum.

The human face, in comparison with that of the lower animals, is characterized by being extended vertically instead of horizontally. This characteristic determines the development of the septum, and the septum determines the development of the nose. The structures entering into the formation of the septum in man are subject to delayed or excessive development. The developmental activity continues, not only up to puberty, but, in a greater or less degree, some years afterwards. With that activity there must be an increase of newly formed blood vessels, resulting in a greater tendency to epistaxis and to deformities of the septum, as shown by the formation of ridges, spurs, and deviations. The development of the septum varies with the type of race; the higher the type the more prolonged is the developmental activity and the more common are the septal deformities.

It has been necessary for me to enter into nose-bleeding as peculiar to the human race as it is the cardinal point. It is difficult to remember any condition of the septum we are called upon to treat that is not vascular in origin.

In a paper strictly limited in words it is possible to mention only the more common of these conditions—such as hæmatoma, abscess, fibro-angioma, septal thickening, out-growths, ridges, spurs, crests, and, last but not least, deflections of the septum. In the group of fibro-angiomata must be included not a few of those cases diagnosed and treated as sarcoma. Further, in this group must be included the "bleeding polypus of the septum." Remembering the papers which have been written, the discussions that have taken place, the time that has been spent by general practitioners in absorbing that literature on this and similar simple septal growths, how true becomes the

difference drawn between the general practitioner and the specialist—the one always struggling to make less and less about more and more, the other always straining to make more and more about less and less.

Deflections and deformities of the septum are so common that the observation of Pliny might be amplified by stating that man—that is, civilized man—is the only creature in which the septum of the nose is not perpendicular. The higher we go in the human race the more correct this statement becomes. The collective result of independent investigations of a large number of human skulls has shown that deformities of the septum are present in 80 per cent. of European skulls. Those investigations were made on dried specimens in which the cartilage was generally absent. Clinical experience teaches us that some irregularity of the cartilaginous portion of the septum is the rule rather than the exception; so that in the higher types of races the abnormal becomes the normal. On the other hand, statistics based upon the examination of skulls of the lower types showed the reverse—the septum was free from deflections and irregularities in 80 per cent.

This "sorrow of the septum" has been handed down to us in art from the days of Pliny. Some scientists, after taking the most minute measurements of the nose of the Venus de Milo in the Louvre, came to the conclusion that the septum was not absolutely in the plumb. It is conceivable that had the missing arms, which have given rise to so much discussion among would-be restorers, been present, Venus, instead of holding up her drapery, would have had the left arm uplifted and holding a mirror, and the forefinger of the raised right hand adjusting the pros and cons of undergoing a submucous resection of the nasal septum.

In making a routine examination of the nose in all cases of affections of the ear, nose, or throat, it is truly remarkable how frequently we meet with ridges, spurs, and deformities of the septum, causing no inconvenience, no symptoms, and in no way material to the case, while their presence is not known to the patient. On the other hand, it is equally remarkable that, in the eyes of some rhinologists, the very presence of a spur or a deviation is a menace to the health of the patient, and that some orthopaedic surgery in the nose would cure almost any malady. Time will not permit me to enter into detail of the indications and contraindications for surgical intervention. Experience has shown that the nasal symptoms complained of are frequently in no way due to any irregularity of the septum that may be present, and that they can be completely removed by other means without removing or operating upon the nasal septum. Those other means must be left for another occasion.

This brings me to the much smaller group of cases in which orthopaedic surgery upon the septum is called for. First of all the choice of the operation. Here again time will not permit me to enter into the relative merits of the numerous operations that have been devised for the correction of septal deformities, and of the one for the removal of the offending septum. It is now some twenty years since the operation for the removal of the septum, bony as well as cartilaginous, by submucous resection was introduced. The number of instruments that have been devised for the operation, and the number of septa that have been dealt with by submucous resection, justify the statement that it would be difficult to mention an operation in minor surgery that has received so much attention, and (judging by the way it is referred to by the younger surgeons as the septum operation), we might add, to the exclusion and in ignorance of all other operations upon the deformed septum. It has become a fetish. There is increasing evidence that the general public has had enough of the removal of pieces of gristle from the nose. The end-results, however gratifying to the surgeon, are not always equally satisfactory to the patient.

The operation from the first appeared to me to be faulty surgery; inasmuch as it deprived the patient of a rigid septum and thereby impaired the nose as an organ of respiration. The nasal passages after the operation are left at times too patent, the septum too thin, and patients complain of symptoms due to the flapping of their membranous septum in the passage of air. Further, in

spite of reduction of the anterior ends of the middle turbinated bodies at the time of the removal of the septum, very considerable hypertrophy of these structures has ensued. The patient, as the result of the above, then seeks relief for tightness across the upper part of the nose and nasal obstruction.

The operation is extremely difficult where it is most needed. In the worst rumpled septa, however experienced and skilful the operator, sloughing and perforation often result, leaving the last state of that septum worse than the first. The cases in which it is least needed yield the best results; those in which it is most required are at times wisely left alone. Further, general anaesthesia for operations upon the upper air passages, particularly when prolonged, is attended with greater risk. Lastly, it is questionable whether the end-results of rectifying the nasal septum by removing it by submucous resection are any better than those formerly obtained by other operations.

To avoid unnecessary discussion let me say I am in favour of a limited submucous resection in removal of spurs and ridges, and of the septum when badly rumpled. The procedure I follow when orthopaedic surgery on the septum is inevitable may be described as a modification of Moure's operation.

Owing to their complete obsession by the submucous resection and removal of the septum there must be among the rising generation of rhinologists many who have not seen Moure's operation performed, and have not even seen the instruments. In spite of the arguments about the resiliency of cartilage, I may claim to have got good results, and certainly never the unfortunate troubles that have followed submucous resection and removal of the septum. Bear in mind that Nature has decreed that the nasal septum of civilized man is not to be in the plumb; that would be, as I have shown, abnormal and peculiar to the savage types. Therefore, why should we try to improve upon Nature by depriving a person of a rigid septum—necessary for respiration?

The results of the submucous resection and removal of the septum taken on the whole are not satisfactory; for reasons I have given it is not sound surgery. The paper has been written to review the position and to promote discussion. The time for half-truths has gone by; I cannot expect those who have spent years in acquiring skill in the submucous resection operation to agree with me, and I shall be sadly disappointed if this paper is not criticized.

#### DISCUSSION.

Dr. W. S. SYME (Glasgow) said that partial nasal obstruction was not detrimental to hearing in a marked degree. The aim of the operation should be functional rather than anatomical. He emphasized the importance of removing deformities of the lower part.

Mr. HERBERT TILLEY (London) said that no inconsiderable amount of the disrepute that had fallen on the operation was due to its imperfect performance. He instanced four of the common causes of failure: (1) Leaving untouched a prominent premaxillary crest in the postero-medial region of the vestibule, against which the ala nasi was drawn during inspiration. (2) Neglect to remove a prominent teat-like prominence at the junction of the vomer, central plate of the ethmoid, and the cartilage of the septum. (3) Failure to reset a posterior deviation of the central plate of the ethmoid and vomer. (4) The overlooking of a deviation of the bony "nasal crest" of the superior maxilla. If the cartilage alone was removed, the septum would still be held across to the crest when healing was complete. Mr. Tilley held that in long-established deafness due to what was termed "chronic otitis media," resection of a deviated septum produced no improvement in the hearing. If, however, inflation of the tympana brought about a temporary but definite increase in hearing, then any form of nasal obstruction should receive appropriate treatment, and good results might be anticipated by removing catarrhal conditions of the middle-ear cleft. No condemnation could be too severe of those who performed submucous resections in cases of genuine oto-sclerosis. Such operations must be due either to ignorance of the pathology

of that condition or to other considerations which it would be scarcely worth while to discuss. To abuse the confidence of patients by telling them that the proposed nasal operation might not cure the deafness but it would probably prevent it from getting worse, at least suggested the question, "How can you prove that?" Such operations not only added to the "sorrows of the septum," but also to those who were jealous of the fair fame of this special department of medicine.

Mr. NORMAN BARNETT (Bath) found that rigidity of the septum rapidly returned after submucous resection, and that failure in procuring a good result was often due to overlooking enlarged posterior ends of the inferior turbinates.

Mr. ERNEST B. WAGGETT (London) said that the septum operation was not performed often enough, nor well enough. He added that leaving a spur from the vomer was a common cause of failure.

Mr. E. D. D. DAVIS (London) spoke glowingly of his personal experience of undergoing submucous resection; his previous troubles of nasal obstruction and prolonged "colds" had quite disappeared. He mentioned that one reason of unsuccessful result was that the septum was not always responsible for the obstruction. He urged submucous resection before operations on the sinus, and particularly on the ethmoid, if the septum was deflected, both to provide access at the time of operation and to facilitate drainage afterwards.

Dr. IRWIN MOORE (London) said that, in his opinion, the secret of success in the operation of submucous resection of the septum was the removal of as little of the cartilage as possible. The majority of deviated septa were developmental in origin, the obstruction being caused by the lower margin of the cartilaginous septum slipping off the superior maxillary ridge, followed by ossification in this situation. In these cases he separated the cartilage with scissors from the maxillary ridge, after which he removed the bony mass obstructing the inferior meatus. The "spring" (deviation) of the cartilage not removed could be counteracted by incising the cartilage (from above downwards) at distances of a quarter of an inch (from before backwards), which allowed the attached segments to adjust themselves in the vertical position. If this method was pursued no "flapping" of the septum would follow the operation. He had operated upon a very large number of patients and seen a great deal of the work done by other operators, and he was satisfied that the operation of submucous resection of the septum, as carried out in the majority of cases, was a credit to the specialty in this country.

Dr. DOUGLAS GUTHRIE (Edinburgh) advocated the use of local anaesthesia in this operation. Dr. W. HILL (London) said that the exigencies of hospital practice necessitated the extensive resort to local anaesthesia in septal and other nasal operations. In private practice, however, he relied mostly on a general anaesthetic, as a certain number of patients complained afterwards of the want of absolute efficiency of local anaesthesia. In his own person he would prefer a general anaesthetic if he had to have a septal operation. Local anaesthesia was much more frequently and extensively used on the Continent and in America than here, not merely for septal operations and tonsillar excisions, but for such major procedures as radical antral and mastoid operations and excisions of the larynx. Dr. SCOTT STEVENSON (London) advised deep general anaesthesia. Mr. H. BELL TAWSE (Nottingham) said that, with the exception of two cases in children under 14 years of age, he had for the past twenty years used local anaesthesia. Referring to "flapping" as an occasional sequel of submucous resection, he asked how it might be remedied. Mr. E. B. WAGGETT (London) replied that such a condition was readily cured by making a perforation in the posterior part of the septum sufficiently large to allow the air pressure to be equalized in both nostrils. Mr. DONALD WATSON (Bradford) favoured local anaesthesia; his personal experience under it was that he felt no discomfort, only a sensation of cracking of bone.

Mr. A. R. TWEDIE (Nottingham) mentioned that one of the reasons for lack of success in the operation was a pre-existing collapse of the alae nasi. He referred to the iniquity of operating on the septum in oto-sclerosis and giving the patient to understand that the hearing would benefit. In the case of catarrhal deafness not only did he require improvement in hearing after inflation before advising operation, but also a positive Gellé test and a mobile membrane, always assuming that bone conduction was at least normal. He used local anaesthesia as a general rule, even in children of 8 years. He recommended an operation for access in intranasal operations. After removing the deformity he replaced any cartilage he could.

Mr. KELSON (London) objected to packing the nose after operation.

The PRESIDENT (Dr. Brown Kelly) pointed out that nasal obstruction often varied from day to day, was frequently mainly due to turbinal turgescence, even though the septum was deflected. Submucous resection was performed not only to widen the narrow nostril but also to narrow the too-open side. He deplored mutilating the inferior turbinates, and did not favour operation in patients younger than 17 years of age.

Dr. JOHNSON HORNE in reply, expressed his pleasure at the favourable way in which his paper had been received. One speaker had completely and concisely expressed one contention of the paper—that an operation upon an obstructing nasal septum should aim at a functional and not at an aesthetic result. Regarding the choice of local or general anaesthesia, his guiding principle had been that in hospital such work should be done as would be required in private practice; in the latter general anaesthesia would be preferred more often than not. He was glad that reference had been made to the enlargement of the posterior ends of the turbinated bodies as a factor in nasal obstruction. Had time permitted, that was one of the causes, other than irregularity of the septum, he had intended to touch upon. The importance of posterior rhinoscopy as a routine part of an examination of the nose could not be overstated, and the surprises encountered at times would fill a chapter.

## ACUTE RETROPHARYNGEAL ABSCESS IN CHILDHOOD.

BY

DOUGLAS GUTHRIE, M.D., F.R.C.S.,

Surgeon to the Ear and Throat Department, Royal Hospital for Sick Children, Edinburgh.

Two varieties of retropharyngeal abscess are distinguished in most textbooks. Bokai,<sup>1</sup> whose classical paper on the subject deals with 287 cases, showed that many were of lymphatic and not of spinal origin. Indeed, the spinal variety is relatively rare, coming to the notice of the surgeon on account of well marked signs of tuberculosis of the cervical vertebrae, and, as a rule, presenting little difficulty in diagnosis. The acute variety of abscess, on the other hand, is probably fairly common. Insidious in origin and often showing no characteristic sign or symptom, it frequently escapes diagnosis, or is only discovered at *post-mortem* examination. The condition perhaps more frequently escapes recognition than any other acute disease in childhood, and, if untreated, almost invariably ends in death. On the other hand, when a retropharyngeal abscess is recognized and opened the prognosis is good and the patient recovers rapidly.

**Anatomical Data.**—In order to understand the pathology of retropharyngeal abscess various anatomical facts must be kept in mind. The prevertebral fascia passes in front of the cervical vertebrae and prevertebral muscles, and separates the visceral compartment containing the trachea and oesophagus from the vertebral compartment containing the vertebrae and muscles. In front of the prevertebral fascia, and closely adherent to it in the middle line, is the mucous membrane of the posterior wall of the pharynx. Between the fascial and mucosal layers, in the potential space on either side of the mid-line, known as the space of Gillette, lies a group of lymphatic glands.

Those are retropharyngeal glands, which are present in infancy, but gradually atrophy and disappear as the child grows older. They are in direct communication with that chain of glands which lies behind the internal carotid artery sometimes called the posterior carotid chain.

**Pathology.**—Infection of these posterior carotid glands may readily pass to the retropharyngeal glands and give rise to abscess formation; this is probably the usual sequence of events in acute retropharyngeal abscess. In two-thirds of the cases there is obvious enlargement of cervical glands; this enlargement may be of tuberculous nature. Although McLean and von Hofe<sup>2</sup> state that retropharyngeal lymphadenitis is rarely tuberculous, unless accompanied by vertebral caries, we have in two cases of retropharyngeal abscess found definite evidence of tuberculosis in the cervical glands, which were subsequently excised. The most frequent cause of abscess formation, however, is the streptococcus, and this organism may be isolated from the pus in the majority of cases. Waugh<sup>3</sup> regards the tonsil as the source of infection, as the condition is never found in children whose tonsils have been removed. Definite enlargement of the tonsils is present in about 80 per cent. of patients who suffer from retropharyngeal abscess. Trauma is a possible cause; thus Alexander<sup>4</sup> saw two cases following the attempted removal of adenoids, and Bokai includes a case caused by the impaction of a metal button in the nasopharynx. Another possible cause of retropharyngeal abscess is the direct spread of pus from the middle ear. Middle-ear suppuration was present in one-fifth of our cases, but there was also glandular enlargement in each, so that no case could be regarded as "otitic pharyngeal abscess," a rare condition which has been described by Dan McKenzie<sup>5</sup> and others. Even rarer is the acute non-tuberculous osteomyelitis of the cervical vertebrae observed by Kirmisson.<sup>6</sup>

**Etiology.**—The condition appears to be commoner in boys than in girls, and is said to be more prevalent in winter, although eight of the twenty patients noted in the accompanying table came to hospital during the months of May, June, and July.

Table to illustrate the Writer's Series of 20 Cases of Retropharyngeal Abscess.  
(Boys 14; Girls 6.)

| Age.                      |     |     |     |     |     |
|---------------------------|-----|-----|-----|-----|-----|
| 0 to 1 year               | ... | ... | ... | ... | 7   |
| 1 to 2 years              | ... | ... | ... | ... | 4   |
| 2 to 3 "                  | ... | ... | ... | ... | 3   |
| 3 to 4 "                  | ... | ... | ... | ... | 2   |
| 4 to 5 "                  | ... | ... | ... | ... | 1   |
| 5 to 6 "                  | ... | ... | ... | ... | 1   |
| 6 to 7 "                  | ... | ... | ... | ... | 2   |
| <b>Diagnosis.</b>         |     |     |     |     |     |
| Dyspnoea                  | ... | ... | ... | ... | All |
| Dysphagia                 | ... | ... | ... | ... | 3   |
| Enlarged glands           | ... | ... | ... | ... | 13  |
| Otitis                    | ... | ... | ... | ... | 4   |
| Nasal obstruction         | ... | ... | ... | ... | 6   |
| Epistaxis                 | ... | ... | ... | ... | 1   |
| Temperature over 100° F.  | ... | ... | ... | ... | 8   |
| Temperature under 100° F. | ... | ... | ... | ... | 5   |
| <b>Result.</b>            |     |     |     |     |     |
| Abscess opened (cure)     | ... | ... | ... | ... | 14  |
| Spontaneous rupture       | ... | ... | ... | ... | 2   |
| Swelling subsided         | ... | ... | ... | ... | 1   |
| Death (sudden)            | ... | ... | ... | ... | 3   |

The organism was found in 8 cases (streptococcus in 6; pneumococcus in 2).

**Age Incidence.**—Most of the patients are under 1 year of age. McLean and von Hofe report 77 cases, of which 55 (71 per cent.) were under 1 year, while Frank<sup>7</sup> relates 74 cases, of which 4 were adults. The remaining 70 were all under 10 years, and 66 (90 per cent.) under 3 years of age, the youngest patient being an infant aged 3 weeks. Koplik<sup>8</sup> observed 77 patients under 10 years of age.

**Symptoms.**—The most characteristic symptom, almost invariably present, is difficulty of breathing. This may be attributed to bronchitis or laryngeal diphtheria, and may even lead to the fatal mistake of performing tracheotomy, as in one of the cases reported by Pearson.<sup>9</sup> If the abscess extends far up into the nasopharynx it will, of course, cause nasal obstruction, but, as a rule, the abscess tends to "point" just opposite the upper aperture of the

larynx. The larynx in the infant is relatively small and is situated at a higher level than in later life, so that dyspnoea is readily produced. Difficulty of swallowing is not so common as dyspnoea. It was noted in only 4 of 77 cases (McLean and von Hofe), and in 3 of the present series of 20 cases. The early stages are often marked by croupy cough and a "throaty cry, resembling the quack of a duck"; the latter is often described, though seldom heard. The head is held stiffly and often inclined towards the affected side. The temperature is seldom very high and may even be normal. The diagnosis, however, is merely a matter of conjecture until the throat is examined. In a good light the observer will note a swelling of the posterior pharyngeal wall to one side of the middle line, but as this is covered by normal mucous membrane it may be difficult by inspection alone to appreciate the altered contour. Digital examination is the most certain diagnostic test, but should not be practised unless one is prepared, if necessary, to open the abscess forthwith, as death during digital palpation has often occurred.

**Diagnosis.**—Considering the vagueness of the symptoms, and the fact that the abscess may escape notice even on inspection, it is easy to understand why the condition often passed undiagnosed. Nasal obstruction and discharge suggest adenoids, and, in my experience, this is the most frequent diagnostic error. As has already been mentioned, the symptoms may closely resemble laryngeal diphtheria, or a foreign body in the larynx may be suspected. Lymphosarcoma of the retropharyngeal region may, of course, simulate abscess, but is much rarer. Cervical scoliosis causes a unilateral projection of the posterior pharyngeal wall, and even in normal subjects, when the head is strongly turned towards one shoulder, a swelling, caused by the transverse process of the second cervical vertebra, may be seen behind the tonsil, as first pointed out by the present writer.<sup>10</sup> In such cases the swelling is, of course, of bony hardness.

**Treatment.**—If left to itself the abscess will cause death from suffocation, or it may rupture and flood the air passages. Should the patient survive this event, death from septic bronchopneumonia may follow, although it is noteworthy that two patients in the present series survived

from the mouth and nose and relief is immediate. Convalescence is surprisingly rapid in many cases.

**Fatal Cases.**—Fatalities during the operation will be largely avoided if the above method is adopted. Of three fatal cases in the present series, the first patient died on the way to hospital (see figure), the second immediately after admission, and the third, a feeble infant, died just after the abscess had been opened. Fatal haemorrhage has been recorded by Sokoloff<sup>11</sup>—a child aged 2—and also by Wylie and Wingrave<sup>12</sup> in a woman aged 21.

#### Conclusions.

1. Retropharyngeal abscess is not an uncommon disease, but is very liable to be overlooked.
2. For the anatomical reasons described, infants are the chief sufferers.
3. Dyspnoea is the principal, and often the only, symptom.
4. The abscess should be opened from the mouth, but no general anaesthetic should ever be used.

#### DISCUSSION.

Mr. BELL TAWSE (Nottingham) referred to a child, aged 4, who developed a retropharyngeal abscess after tonsils and adenoids had been removed.

Mr. E. D. DAVIS (London) had seen retropharyngeal abscess develop some time after efficient enucleation of tonsils. One case was possibly tuberculous. He advocated the use of the Davis gag in opening such abscesses. The head was extended over a sand-bag so that it was lower than the larynx; the gag was then inserted and an excellent view obtained.

The PRESIDENT (Dr. Brown Kelly, Glasgow) asked Dr. Guthrie if it was a fact that the pharynx was attached posteriorly to the prevertebral fascia in the middle line. He did not think so, nor was it his experience to find the abscess on one side or the other of the middle line, but rather diffused behind the pharynx. This was important from the diagnostic standpoint: deep cervical abscesses pointing in the pharynx pushed the deep cervical fascia and the deep vessels towards the middle line and were confined to one side; retropharyngeal abscess pushed these vessels outwards. He emphasized the importance of opening retropharyngeal abscesses without an anaesthetic.

Dr. DOUGLAS GUTHRIE, in his reply, said he was quoting Waugh in suggesting that detonsillized patients were immune from retropharyngeal abscess. He would further investigate the anatomy of the part concerned in view of the President's criticism.

#### CLINICAL MEETING.

DURING the afternoon of July 21st and 22nd a number of extremely interesting and instructive cases were shown by Mr. A. R. TWEEDIE and Mr. BELL TAWSE.

Four cases of laryngo-fissure for epithelioma of the larynx were demonstrated. Periods of from ten years to six months had elapsed since operation without recurrence. Three of these had had one and a half vocal cords removed.

Regeneration of the front of the skull was exhibited in the case of a young man, the subject of acute frontal sinus suppuration in 1923. Osteomyelitis of the frontal and parietal bones developed before operation. The affected areas were incised and drained. The sinusitis was attacked by resecting the septum, clearing out the ethmoids, and performing Howarth's operation on both frontal sinuses, the intersinus septum not being present. X-ray photographs showed the progress of bony restoration.

FIG. 1.—Acute retropharyngeal abscess in child aged 14 months, who died on the way to hospital.

wrapped in a blanket with the arms fixed to the side. A gag is then inserted and the point of a long sinus forceps or peritonsillar forceps plunged into the most prominent part of the swelling and opened in a vertical direction. The operation must be performed rapidly, as the introduction of the gag may arrest respiration by pressing the abscess against the larynx. At the moment of opening the child is turned on his face with the head slightly dependent and the gag is removed. Pus flows

An example was given of non-recurrence of cancer of the tongue in which the growth, involving the right tonsil and pillars, had been excised seven years ago, and the palpable cervical glands had been treated by x rays.

A case of endothelioma of the right nostril and maxillary sinus was treated by 50 millicuries of radium salt in the antrum and 40 millicuries in needles of 2 millicuries each in the right ethmoid for twenty-four hours. There was remarkable stimulation of the growth by the radium, followed in three months by its complete disappearance. This case illustrated Hastings Gilford's view that radium destroys cancer cells by stimulating their growth beyond their viability—that is, by shortening their life cycle.

The views expressed on an example of rhinotalia apperta drew attention to the necessity of excluding such a condition before removing tonsils or adenoids.

An instance of left temporo-sphenoidal abscess causing contralateral paralysis of the right arm and leg, together with aphasia, aroused much interest. Meningitis complicated the issue, and during the illness the cerebro-spinal fluid was turbid, contained polymorphonuclears and organisms, and was deficient in chlorides. The abscess was opened, and recovery was uneventful. Such findings as the above in the cerebro-spinal fluid would appear to have stamped the meningitis as the malignant variety. (See report on combined discussion of the Sections of Medicine, Otology, Neurology, and Laryngology of the Royal Society of Medicine, *Proc. Roy. Soc. Med.*, vol. xviii, Part 3).

Opinions were invited in a case of extensive epithelioma of the hard palate as to whether diathermy was indicated. Mr. NORMAN PATTERSON considered the primary growth amenable to such treatment in spite of the bone involvement, and suggested x rays for the associated glands.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### MIGRAINE AND ACETONURIA.

THE negative result of a careful search throughout the extremely interesting discussion on migraine, reported in the *JOURNAL* of October 30th, and the editorial under "Sick headache" on a subsequent page, for any mention of the association of migraine and acetonuria prompts me to put forward a plea for the routine examination of the urine for acetone, in addition to ophthalmic and other investigations, in all cases of sick headache.

In the pursuit of a busy country practice on the northern slopes of the South Downs examination for acetonuria of all cases of headache and vomiting coming under observation has elicited the presence of acetone bodies in far too big a proportion of cases for the possibility of mere coincidence.

The following case, recently under observation, would appear to be of sufficient interest to be reported in detail.

A professional man, aged 42, physically fit, with no previous history of migraine, had a sudden attack while walking in his garden. Giddiness, headache, and a visual disturbance, described by the patient as partial blindness, came on so quickly that he experienced difficulty in staggering back into the house, where he collapsed on a bed without undressing. Vomiting supervened, and giddiness was so distressing that he was unable to sit up unaided. The possibility of hyperpæsis was considered, but the maximum systolic blood pressure proved to be 130 mm. The temperature was subnormal, and examination of the heart, lungs, and abdomen failed to elicit any abnormal physical sign.

Routine bedside examination of the urine for albumin, sugar, acetone, and diacetic acid, by means of capillary tubes containing appropriate reagents, revealed the presence of excess of acetone as the only abnormality.

While this examination was being made the patient complained that the least movement of his head produced nausea resembling sea-sickness, both the bed and walls of the room appearing to move as if in a seaway.

An alkaline mixture and later glucose were given by the mouth, but as both were vomited, an enema was administered containing two heaped-up teaspoonfuls each of sodium bicarbonate and glucose. Much to the surprise of the nurse who gave the enema a pint and a half was completely retained, the patient passing a semiformed motion some seven hours later. In the meantime improvement was very gratifying, the patient slept and dozed

alternately, and was then able to get up without nausea or giddiness to go to stool. Glucose, alkali, and then light food were given by the mouth; in twenty-four hours the urine was free from acetone, and the patient felt himself again.

Routine examination of the urine for acetone of all children attended since resuming civil practice after the war has revealed many cases of vomiting associated with acetonuria. These attacks appear to be due to excitement, indiscretions of diet, and intestinal stasis, and can actually be prevented or controlled by careful dieting and a course of alkalis. The attack itself is best relieved by administration of glucose. Some of these children, now well on in adolescence, suffer from sick headaches without vomiting. These attacks are also associated with acetonuria, appear to have the same etiology, and to be relieved by the same treatment as the periodic attacks of vomiting of early childhood.

Routine examination for acetonuria in these cases over a period of years has afforded me a most fascinating problem for speculation, study, and possible further research.

#### ADRENALINE AND THE STOPPED HEART.

SO much interest has recently been evoked as to the effect of adrenaline in reviving the heart in moribund cases that we are prompted to add our testimony as to its efficacy in the following case.

A Chinese farmer, aged 36, was admitted on September 20th complaining of distension of the abdomen and swelling of the legs, which had been going on for about a month. He lived a quiet and sober life and denied any venereal infection.

The abdomen was much enlarged and palpation elicited well marked fluid thrill. The distension was so great and with venous engorgement that the colour of the abdominal skin was purpuric. Before paracentesis abdominis could be performed at 5 p.m. on the same day, he suddenly became breathless and lost consciousness. He was found pulseless and no heart sounds could be heard on auscultation; 10 minims of a 1 in 1,000 adrenaline solution were injected into the heart and artificial respiration begun; after about five minutes the heart sounds became audible again, the pulse returned, and he regained consciousness. He died a second time at 12 midnight—that is, five hours after the adrenaline was given. We rather regretted we did not give him another injection and watch whether the heart would respond again to that stimulant. As the relatives refused a post-mortem examination the cause of the ascites still remains obscure.

#### ACUTE SUFFOCATIVE PULMONARY OEDEMA.

THE following case may be added to those which have recently been published in the *JOURNAL*.

A married woman, aged 54 years, has been under my care for over five years on account of myocardial degeneration and arteriosclerosis. During the last five months she has had twelve attacks of acute suffocative pulmonary oedema. The attacks always come on at about 9 p.m., soon after she has retired to bed. They are very typical. She sits in bed looking desperately ill, and with a vessel in her lap, into which she coughs frothy, blood-stained fluid. She is grey and pallid, with a cold sweat on her face and chest. The pulse is regular, rapid, and feeble. Râles are heard all over the lungs.

Each time I have given a hypodermic injection of 1/4 grain of morphine and 1/100 grain of atropine sulphate. In about half an hour she is breathing easily, the cough has stopped, the pulse is slower and stronger, and in about two hours she is asleep. The next morning she feels practically none the worse for what she has gone through the night before.

My experience is the same as that of Dr. W. W. MacNaught (*BRITISH MEDICAL JOURNAL*, October 30th, p. 780) in that the onset is very sudden and without warning symptoms, that there is no loss of consciousness and no general oedema, and that morphine and atropine given hypodermically control the attacks.

## Reports of Societies.

### THE EXANTHEMATA.

At the Medical Society of London, on December 13th, a discussion took place on recent advances in the etiology, diagnosis, prophylaxis, and treatment of the exanthemata. Sir HUMPHRY ROLLESTON, President of the Society, was in the chair, and called upon his brother to open the debate.

Dr. J. D. ROLLESTON said that in no field of medicine had the collaboration of clinicians and laboratory workers been more fruitful than in the acute exanthemata, though the fruit had not always attained maturity. With regard to the etiology of scarlet fever three rival schools might be mentioned: the Italian school, who maintained that the pathogenic agent in scarlet fever was a diplococcus which was always present in the blood, cerebro-spinal fluid, and bone marrow during the eruptive period; the Dicks and others in the United States, who maintained that a variety of the streptococcus was the organism; and certain workers in Budapest and in Zürich, who deprecated the excessive importance attached to bacteriological research and maintained that scarlet fever was not due to a specific organism, but depended on a variety of different causes. The bacteriological diagnosis of this disease was not so simple a matter as that of diphtheria. His experience of the Dick reaction was that it was too frequently negative in the first few days of the eruption and too frequently positive in convalescence to be of great diagnostic value. Nor did he think the Schultz-Charlton test a very trustworthy guide. In discussing the prophylaxis of scarlet fever it must be borne in mind that the condition was not highly contagious; various preventive measures had received undue credit owing to failure to realize this fact. Numerous enthusiastic reports of the treatment of scarlet fever by a specific streptococcus antitoxin had been made, but he regarded as an instance of excessive zeal the claim of some writers that antitoxin should be administered as routine treatment. Unless a specially concentrated serum were used—and the cost of this was considerable—there was always a risk of the serum reaction being far more severe than the original attack of scarlet fever. Altogether, with regard to scarlet fever, his conclusions were that the *Streptococcus haemolyticus scarlatinae* described by the Dicks had more claim than any other organism to be regarded as the causal agent; that active immunization by injection of scarlatinal toxin was still in the experimental stage, but was full of promise, and that the use of concentrated scarlet fever antitoxin deserved trial from an early stage in all severe cases.

On the etiology of measles there was as little agreement among bacteriologists as on that of scarlet fever. The diplococcus described by Tunnickliff was more likely to be the causal organism of measles than any other hitherto described. The bacteriology of measles was not yet sufficiently simple or firmly established to be of service to the clinician. Prophylaxis by the injection of convalescent serum was of great value in affording temporary protection from an attack or in diminishing its severity if it occurred. Immunization, whether active or passive, against measles was specially indicated in the case of ill-nourished rachitic children, among whom the disease was particularly dangerous, but he did not think it necessary to urge its application in well-to-do families where measles usually ran a mild course.

With regard to other exanthemata, varicella was rarely a dangerous disease; he had seen only two fatal cases in twenty-six years' fever practice. The small-pox now prevalent in this country was of a remarkably mild character, but there was no justification for regarding this mild type as a distinct disease, and occasionally it gave rise to a rapidly fatal haemorrhagic form. No discussion on the subject would be complete without an allusion to herpes febrilis and herpes zoster. The viruses of the two conditions, though closely related, were sufficiently distinct to justify a separate etiology.

Dr. R. A. O'BRIEN said that the recent change of policy of public authorities with regard to scarlet fever would probably result in a larger number of cases being treated

at home, so that the consultant and practitioner would have a livelier interest than heretofore in the final diagnosis and treatment and the protection of the household contacts. With regard to etiology, the full proof that the *Streptococcus scarlatinae* was the cause of scarlet fever would require that it should, when inoculated into non-immune subjects, produce the typical disease which should be infectious to contacts. The Dicks and Nicolle had apparently supplied part of the proof, for they each had produced with a culture of the streptococcus what they regarded as typical scarlet fever. Until this culturally produced scarlet fever was proved to be infectious to others, it was not possible to deprive of their last argument those who believed that some other agent caused the spread. He himself had been for long unconvinced, but what had finally broken down his scepticism was the fact that the serum of horses injected with the filtrate made from cultures of the streptococcus derived by a few hundred subcultures from the original patients, contained a specific antibody which in high dilution produced the Schultz-Charlton blanching, and when injected into contacts protected them against scarlet fever and had a definitely specific action on the symptoms of patients suffering from this complaint. With regard to the diagnosis of scarlet fever, the Dick test and the Schultz-Charlton test were of definite assistance in doubtful cases. A positive Schultz-Charlton reaction was practically absolute evidence that the disease was scarlet fever. Unfortunately, in connexion with the negative reaction, there were occasional discrepancies not yet fully understood, and a negative result, though it should suggest a careful reconsideration of the diagnosis, did not definitely exclude scarlet fever. Dr. O'Brien entered into a discussion of some possible explanations of the failures, one being that in a certain number of tests the right dilution might not be used. The optimum amount to use in the Schultz-Charlton test was still not known. With regard to the Dick test, a positive reaction here merely indicated that the patient was susceptible to scarlet fever, and it was therefore compatible with a diagnosis of scarlet fever, but unfortunately again a negative reaction to the strength of Dick toxin at present used did not definitely exclude scarlet fever. In time it might be possible to arrive at such a strength of Dick toxin that a negative response might be held to exclude. It had been difficult to get conclusive evidence of the value of antitoxin in the treatment of scarlet fever; the disease in most parts of the world was now very mild. But if serum were of complete efficacy in the treatment of all forms of early and late scarlet fever, toxic, and with septic complications, evidence would soon accumulate. In the treatment of septic complications it was doubtful whether any serum available to-day was of much use, except that the serum might help the patient over the "toxic" part of his attack and enable him to deal with the "septic" part of it himself. There was sufficient evidence from numbers of hospitals in which serum had been used that antitoxin was effective in the treatment of uncomplicated and toxic cases of scarlet fever, and those who had most used it would continue to do so. With regard to prevention, there was little doubt that Dick-positive reactors could be turned negative, and so protected against scarlet fever, either with from 2 to 5 c.cm. of antitoxin, which gave protection probably for two or three weeks, or by active immunization, which protected for a long period.

With regard to measles, Dr. O'Brien remarked that on the assumption that the green diplococcus of Tunnickliff and others was the causal agent, several horses had been injected with an "anti-serum"; the matter was still in the experimental stage. He added a few words about erysipelas. The haemolytic streptococcus isolated from cases of erysipelas seemed to be serologically indistinguishable from that of scarlet fever, and in rabbits it had been possible to show a certain degree of specific neutralization of the culture which, when injected alone intradermally into these animals, produced a lesion very like human erysipelas.

Dr. FOORD CAIGER was in agreement with Dr. Rolleston's conclusions except as to the value of the Schultz-Charlton reaction as a test in scarlet fever rash. In 1924 he made

a series of tests and found that out of 100 consecutive cases of undoubted scarlet fever the serum, which was supplied by Dr. O'Brien from horses he had immunized with the haemolytic streptococcus, showed positive results in about 90 per cent. The success of that test did not depend, as one might have expected, on the concentration of the serum, but the results were equally or more successful in the higher dilutions. With regard to the Dick test, his experience at the South-Western Hospital was quite on the lines that Dr. Rolleston had indicated; the majority of cases coming into the hospital reacted positively, and then they were rather disappointed in a number which failed to show immunity at the time expected, though ultimately a large proportion did become immune. Reports of observations made in America led them to expect that the test would show a negative reaction at an earlier date than it actually did. It had been a satisfaction to him that the Metropolitan Asylums Board should have altered its policy in dealing with measles. Having regard to the fact that scarlet fever admissions were very much larger than those of measles, it seemed a pity that a disease like scarlet fever, which had about 1 per cent. mortality, should take up beds which might be more usefully allocated to a disease like measles, with about 10 per cent. mortality. A larger number of measles cases would now be admitted at the expense of scarlet fever cases. The connexion between varicella and herpes was interesting, and he was sorry that Dr. Rolleston could not throw more light on the subject than to suggest that the concurrence of eruptions was a pure coincidence.

Dr. F. PARKES WEBER asked whether any case had been known in which tuberculosis followed an attack of measles when that attack had not been accompanied or followed by a bad bronchopneumonia or pneumonia. A bad attack of bronchopneumonia did predispose to tuberculosis or aggravated a quiescent condition. As to the connexion between varicella and herpes zoster, an attack of herpes zoster was followed not rarely by an outbreak of disseminated vesicles on the skin. Little attention was usually paid to these, the patient was not frightened about them, and it was only by accident if the doctor's attention was drawn to them at all. It was not possible yet to be sure that this should be considered as an attack of varicella. He had heard of and seen a few striking cases in which the connexion seemed to be almost certain, but, of course, it was difficult to exclude chance.

In further discussion, Dr. LENNOX WAINWRIGHT asked what result would be obtained if the Dick test were applied to German measles, often confused with scarlet fever. Dr. GEORGE GRAHAM asked at what stage the streptococci, almost invariably present in scarlet fever, disappeared. Dr. C. E. LAKIN commented on the usefulness of the Schultz-Charlton test in deciding as between scarlet fever and enema and other rashes. Mr. ZACHARY COPE asked what recent work had been done on the relationship between tuberculosis and measles; he believed tuberculosis had been observed to follow measles much more commonly than to follow scarlet fever or other exanthemata. Sir J. DUNDAS-GRANT spoke of the case with which scarlet fever patients could be isolated in the family, as compared with measles, where isolation at home was much more difficult. Sir HUMPHRY ROLLESTON asked whether there was any justification for thinking that the different varieties of scarlet fever might be due to different types of the haemolytic streptococcus, and whether, if the Schultz-Charlton reagent did not comprise all these types, this might explain its failure in some cases.

Dr. J. D. ROLLESTON, in replying to the discussion, said that recent work by German observers claimed to show that measles did not give rise to tuberculosis so often as had been thought. With regard to the treatment of erysipelas, he expressed himself disappointed with the anti-erysipelas serum, and also with antistreptococcal serum generally in the complications of scarlet fever.

Dr. R. A. O'BRIEN, also in reply, said that in distinguishing scarlet fever from German measles and enema rashes serological methods might help to some extent. If streptococci were found and the Dick and Schultz-Charlton tests were both positive, one should be careful before saying that the case was not scarlet fever. Unfortunately, the

negative did not hold so definitely, except that if haemolytic streptococci were not present the chances were that the case was not scarlet fever. The fact that streptococci were almost invariably present in scarlet fever was not always borne in mind by clinicians when faced with these troublesome rashes. There were not enough observations to say dogmatically when streptococci disappeared—apparently during the second or third week. It was attractive to think that different serological types were responsible for different phases of scarlet fever. In the case of diphtheria, from time to time it had been conjectured that there were different types of the diphtheria bacillus, and that the antitoxin might protect against one strain and not against the others. That, however, was almost certainly fallacious, and he rather thought it would be so in scarlet fever, but he would like to see a concerted investigation in which in the unexpectedly Dick-negative and Schultz-Charlton-negative cases the organisms might be isolated and worked out in their agglutination groups.

### ABNORMAL BLOOD PRESSURE AND EAR DISEASE.

A COMBINED meeting of the Sections of Otolaryngology, Medicine, and Neurology of the Royal Society of Medicine was held on December 3rd, when a discussion on the relation of abnormalities of the blood pressure to diseases of the ear was opened by Sir WILLIAM MILLIGAN.

Sir William Milligan stated that the vascular supply of the internal ear formed a terminal or closed circulation, anastomosis with the middle-ear vessels being negligible. The two main branches of the labyrinthine artery supplied the entire vestibule and the canals, the sacculle receiving a separate supply from an independent branch. The blood left the internal ear by a vein in the internal meatus and draining the cochlea and vestibule, a vein running along the aqueductus cochleae and draining the cochlea, and a vein passing along the aqueductus vestibuli, draining the semicircular canals and the vestibule. This arrangement materially lessened the risk of back pressure; one segment might be put out of action by embolism or atheroma without affecting other parts of the ear. Any pathological abnormality was, therefore, most likely to affect the cochlea or the vestibulo-canalicular systems. The auditory nerve was the most sensitive of the cranial nerves, and responded to variations in arterial pressure very readily, as shown by sudden and transient attacks of vertigo and tinnitus; the latter might result from either high or low blood pressure and was usually bilateral unless due to a local organic lesion. Sudden vertigo and rushing tinnitus gave often the first danger signal of high blood pressure. The transient vertiginous attacks in high pressure were probably due to arterial spasm with resulting labyrinthine anaemia, and not to a definite exudate. Nicotine had a marked effect in raising blood pressure by inducing contraction of the arterioles, partly by stimulating the medullary vasomotor centre, and partly by local action. Repeated vertiginous attacks of the labyrinthine type, following sudden head movements and unaccompanied by deafness, were frequently forerunners of fatal angina pectoris. Persistent tinnitus in middle-aged, plethoric, and constipated women leading sedentary and luxurious lives was a signal of commencing high-pressure. Sudden severe vertigo in petit mal, migraine, and severe nerve shock was probably due to angio-spasm, with resulting labyrinthine anaemia; such vertiginous attacks were also common in hypertension. When the symptoms were permanent secondary changes due to effusion or to toxic infection were probably present. In Bright's disease and certain cardiac conditions an exudate formed suddenly in the tympanic cavity, with deafness, tinnitus, and possibly vertigo; such hydrops tympani might be the first indication of contracted kidney in middle-aged men. Hypotension occurring in such conditions as severe anaemia, neurasthenia, and influenza might cause temporary loss of hearing, tinnitus, and vertigo from venous stasis in the internal ear. Primary disease of the internal ear was comparatively rare, and most cases of tinnitus and vertigo, with or without deafness, were due to vascular abnormalities associated with organic disease elsewhere in the body. In

all cases where the clinical symptoms did not suggest internal ear disease there should be a detailed examination of the heart, the kidneys, and intestinal tract; records of blood pressure should be made.

Dr. Lewis Smith could not agree with Sir William Milligan's conclusions as to the frequent relation between abnormal blood pressure and ear disease. For the purposes of this discussion he had carefully analysed a series of cases examined by himself. In 50 cases of hyperpiesis in adults, with a systolic blood pressure of 200 mm. or more, he had found that only ten patients mentioned giddiness among their prominent symptoms. In 20 cases of pronounced low pressure in adults, with a systolic blood pressure of 110 mm. or lower, only four mentioned vertigo. In 50 cases complaining of vertigo as their main trouble, he found only 13 whose blood pressures were markedly above or below the normal, and in 40 cases of aural vertigo—Ménière's symptom complex—29 showed a normal blood pressure. He considered these figures conclusive evidence against a common causal relation between abnormal blood pressure and ear disease. He discussed the complex causation of vertigo and emphasized the frequency of a nervous factor, either exhaustion or anxiety, in its production. He also laid stress on toxic factors, notably tobacco and alcohol. Some of the cases were undoubtedly epileptic. He dealt in considerable detail with the clinical features of Ménière's symptom complex, in which he thought there was often evidence of organic disease of the internal ear, and discussed various forms of treatment. He pleaded for a more careful investigation of all cases of vertigo, which were often too loosely ascribed to high blood pressure or arterio-sclerosis. In his series of 40 cases, only seven had been correctly diagnosed; a considerable number of the sufferers were living in a quite unnecessary dread of cerebral trouble, and the fear of "strokes."

Dr. W. J. Arne, after commenting on the limitations imposed by the title of the discussion, said he thought he could best promote discussion by adopting an extreme view. He would therefore attempt to defend the view that there was little or no direct relation between disorders of the blood pressure *per se* and disease of the ear. Tinnitus and vertigo were common in disorders of the central nervous system. If auditory impressions succeeded in reaching the medulla they were always perceived in spite of most extensive lesions of the brain stem and cerebrium; hence the presence of deafness indicated a lesion of the ear or eighth cranial nerve, but the localizing value of tinnitus or vertigo without deafness was not certain. The only cases that deserved serious consideration in this discussion were those with deafness and vertigo or tinnitus. The association of these symptoms with disorders of the blood pressure was common, but there was nothing to prove that it was more than an association. There were two possibilities: the degenerative changes might occur in the ear side by side with degenerative processes in other parts, such as the arteries or kidneys, or the degenerative changes might be the results of a defective blood supply to the ear. Whatever their origin it was certain that the same processes and exactly the same symptoms might and did occur in persons with high, low, and normal pressures. They were too apt to correlate the blood pressure with certain symptoms. If a patient with high blood pressure had a stroke, it was thought to be due to haemorrhage, whereas if the pressure was low thrombosis was diagnosed; but thrombosis was low common in the diseased arteries of persons with a high blood pressure. Sir William Milligan was right when he said that the symptoms they were discussing called for a complete overhaul of the patient; the fact that the pressure was often low or normal did not justify the conclusion that there was little connexion between these symptoms and certain general disorders. Dr. Adio felt sure that the greater number of older patients with these symptoms had also arterial disease. His point was that the blood pressure was of little importance, the state of the vessels all-important. Hypotension in debilitating diseases sometimes caused symptoms that were certainly aural in origin, but these cases were rare. Attacks of dizziness or giddiness were frequent in patients with an unstable vasomotor mechanism or other circulatory dis-

turbance, and in various functional and organic diseases of the nervous and other systems, but it was probable that the vertigo in most of these cases was of central origin. In many cases the site of origin of the symptoms was uncertain; even when they were certainly of aural origin the blood pressure varied. Hence they might conclude that though symptoms referable to the ear were commonly associated with general circulatory disturbances, the relation between disorders of the blood pressure *per se* and actual diseases of the ear was at most indirect and relatively unimportant.

Mr. G. J. Jenkins said that such auditory and vestibular symptoms and signs were only part of the general manifestation of blood pressure insufficiency. Patients might continue in apparent health with blood pressures considerably above or below normal, and without any auditory symptoms. It seemed that our views as to the relation of blood pressure to these symptoms must remain, to a large extent, speculative until we found a measure of efficiency of the blood pressure in a particular individual. He doubted whether very high systolic pressure had ever produced ear symptoms without there being some local change. With high pressure compensating for the existence of diseased vessels there was often evidence of labyrinthine disease; this local affection was probably part of the general disease, and not due to the blood pressure. Bone conduction was much diminished, and there was loss of high tones, the low tone limit being about normal. The conversational voice might be well heard, though whispers were almost inaudible. Vestibular tests often gave normal results. Most of these patients carried on well except for diminished hearing, but some had persistent tinnitus and dizziness, and in others it was difficult to decide whether their symptoms were due to inefficient blood pressure or to labyrinthine disease. When such affection of the labyrinth was more marked in one ear, it was possible that this organ might be affected by abnormally low pressure earlier than the other. The tinnitus and deafness might be limited to that ear, with nystagmus to the opposite side, and other localizing signs. This group of unilateral cases supported the suggestion that the fall in blood pressure caused the ear symptoms by affecting the labyrinth. Mr. Jenkins had found no evidence of pathological changes being caused in the ear by too high or too low pressures.

### THE HOSPITAL AND PUBLIC HEALTH.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on November 26th, Dr. S. MONCKTON COPEMAN, the President, occupying the chair, Dr. GEORGE F. BUCHAN read a paper on "The hospital in relation to the public health."

Dr. Buchan estimated that, for a community of 100,000 inhabitants, of average age and sex constitution, 250 hospital beds would be required for public health services, 177 for the notifiable infectious diseases, 28 for maternity and child welfare, 13 for school medical work, 3 for venereal diseases, and 29 for further hospital treatment of certain cases of measles, whooping-cough, orthopaedic cases, rheumatic fever and heart diseases, and cancer. Three-fifths of this accommodation was already provided in isolation and tuberculosis hospitals and sanatoriums. The remaining two-fifths would be similar to that already provided by the voluntary general and special hospitals throughout the country. Discussing the methods of provision of these additional beds, Dr. Buchan hoped that the question would not be further complicated, as had been suggested, by the transfer of rate-supported beds from boards of guardians to other authorities which were not always the authorities at present responsible for the consideration of public health problems involving extension of hospital accommodation. The suggested transfer would not unify, but would still leave hospital accommodation under different authorities. Since there were already provided in this country 179,772 beds by local authorities, the need for erection of new hospitals by local authorities would seldom arise. For practical purposes, therefore, the discussion was limited to questions of extension

of isolation hospitals, Poor Law hospitals, and voluntary hospitals. Assuming that the Poor Law hospital would be transferred to the local health authority for the area, he did not think that the problem presented serious difficulty. Extension would obviously be undertaken at the largest hospital, whether isolation, Poor Law, or voluntary, in the area. Doubtless there were still those who considered that infectious and non-infectious cases should not be housed on the same site. Such a view appeared to be opposed, not only to the experience of other countries, but also to the general principle on which the pavilion type of hospital had been established. If such a tenet were accepted it followed that a scarlet fever pavilion should not be on the same site as a diphtheria pavilion, particularly when the increased susceptibility of a scarlet fever patient to diphtheria was borne in mind. It was also contrary to his own experience. In Willesden during the four years 1919 to 1922 there were treated at the Willesden Municipal Hospital, which was built on the pavilion system, 1,617 cases of maternity and diseases of women, 1,541 cases of school children, 1,018 cases of children under 5 years of age, and 260 cases of general diseases of adults, as well as 4,590 cases of infectious diseases, or 9,026 patients in all, without infection spreading from the one side of the hospital to the other. He concluded, therefore, that there was no medical reason why a hospital suitably planned on the pavilion system should not admit all the diseases for which a local authority might make provision. Some might argue in favour of special hospitals for special categories of disease, as opposed to the large general hospital with its necessary special departments. He was one of those who favoured the latter. Multiple hospitals meant multiple equipment and increased cost of administration, with, to some extent, loss of efficiency because of that lack of interchange of ideas and opinions, both generally and in respect of individual patients, between a medical staff engaged in different forms of medical work under a common roof. Another advantage of the single hospital was that a definite economy in the number of beds to be established could be effected. Diseases were not all prevalent at once, and wards set aside for one disease might therefore be utilized from time to time for other diseases when not required for their normal purpose. Local authorities were empowered by the Public Health Act, 1875, to build hospitals for the reception of the sick inhabitants of their district. By the Public Health Act, 1925, they were further empowered to make subscriptions or donations to voluntary hospitals serving their area. Which of these two courses would be followed would depend on the views of the authorities concerned on the relative merits of voluntary or municipal enterprise. As examples of municipal enterprise he cited the Danish State Hospital and the Municipal Hospital at Copenhagen, and stated that, judging from his own observations during the present year, these were as efficient in respect of equipment and staff as the best examples of the voluntary hospital system in this country.

The public health hospital could be best staffed on the same principles as a large voluntary hospital, with specialists in charge of the departments and a sufficient number of resident medical officers for clinical purposes, the general administrative control of the hospital being vested in a medical superintendent. Medical officers entering the hospital service of an authority could make it a career either for hospital administration or for specialism in one or other of the departments, or utilize the appointment as a preliminary experience for general practice. In Copenhagen the heads of the principal departments, including the hospital for infectious diseases, were appointed university professors; Dr. Buchan commended this idea to our own local and university authorities. Dealing with the question of research, the speaker emphasized the need for inquiry into the antecedents of patients and for more intensive investigation of the factors influencing the production of disease. Research also likely to bear fruit was illustrated by the work recently undertaken in Leeds in relation to the post-operative longevity of patients with cancer of the breast. Concurrent investigation into the post-hospital conditions of the patient would also throw valuable light on the extent to which these hindered

recovery, determined relapse, or accelerated the known sequels of the disease.

Dr. J. D. ROLLESTON referred to the practice in Paris of having pavilions for infectious diseases as part of the general children's hospitals, and said that the same principle was followed to a great extent on the Continent. He considered this an advantageous arrangement as it gave the best men an opportunity of devoting their attention to infectious diseases, which had given such excellent results as those of the immunization work done by the staffs of Continental children's hospitals, to which Dr. Monckton Copeman had alluded in his presidential address.

Dr. JANET LANE-CLAYTON referred to Dr. Buchan's estimate of the additional hospital provision required, and asked whether experience actually showed that there was a shortage of beds. Dealing particularly with cancer, she stated that it appeared that there was no delay in admitting patients for treatment in London. If by propaganda patients could be taught to apply while still operable, the need for cancer beds might be increased, but before providing extra beds throughout the country it would be well to know how far in fact there was a need for them.

Dr. ARNOLD referred to the large fluctuations in the number of beds required for infectious diseases, and suggested that if one hospital were used for all varieties of diseases economy in beds could be obtained by using the spare beds for cases which were not urgent and could wait without disadvantage. He thought that the fact that infectious diseases were treated in special hospitals in this country was a result rather of the special circumstances in which official public health measures were initiated than of any definite idea among sanitarians that it was necessary to have separate hospitals.

Dr. CLARE TROTTER supported the idea of a general hospital for infectious and other diseases. With regard to the provision of cancer beds he did not see why advanced cases of cancer should not receive treatment in the same way as advanced cases of tuberculosis. He disapproved of these being left to be dealt with under the Poor Law. He thought Dr. Buchan's paper was of special value in showing that a hospital to which cases could be referred when necessary by the public health department was of definite value to the community; the nature of the disease was of no importance from the public health point of view, as the object aimed at was the end-result—facilities for proper recovery.

The PRESIDENT agreed that it was desirable to get rid of the taint of pauperism associated with Poor Law infirmaries. He could not accept the suggestion that the majority of patients with inoperable cancer found their way into Poor Law institutions. Those that did so, as a rule, were admitted only a short time before death. It was obviously undesirable from the public health point of view that cancer cases, especially when in the stage of suppuration, should be treated in dwellings with a minimum of accommodation. If, under such a scheme as Dr. Buchan had outlined, the difficulties and possible dangers incidental to the care of patients under such conditions could be eliminated a notable advance in hygiene would be attained.

#### VACCINE THERAPY IN GENERAL PRACTICE.

At a meeting of the Leeds and West Riding Medico-Chirurgical Society on November 19th, with Dr. CRAWFORD WATSON in the chair, Dr. W. EDGECOMBE (Harrogate) read a paper on vaccine therapy in general practice.

After referring to the prophylactic and curative sides of immunization, he discussed the specific and non-specific reactions excited by vaccines, and said that while prophylactic immunization depended mainly on the specific reaction, curative immunization by vaccine therapy appeared to be chiefly associated with the non-specific factor. Inasmuch as general, focal, and local reactions might be produced by the injection of a non-specific vaccine, it was not legitimate to assume that a vaccine causing such reactions was necessarily related etiologically to the disease. Three conditions must be fulfilled before vaccine therapy was undertaken in chronic infective

diseases: the organism from which the vaccine was made should be the true causal organism of the disease; the vaccine should be autogenous; and the source of infection should be determined and removed if possible. These principles were exemplified by illustrative cases. The more closely the conditions were fulfilled the greater was the chance of a successful result. Dr. Edgcombe condemned "speculative" vaccines made from the bowel or other sources, on the assumption, without adequate proof, that therein lay the source of infection. Any good resulting from such vaccines must be due to the non-specific reaction, of the same order as the familiar protein shock reaction. His own experience of the vaccine treatment of chronic fibrositis, neuritis, and arthritis, of supposed infective origin, was that in those cases in which no definite source of infection was found "speculative" vaccines made from the bowel were of little use. In those cases where a definite focus of infection was found, but was not removed, the results were equally poor. In those cases in which a focus of infection was found and removed the results were good. A similar or greater number of cases of the same type, however, recovered equally well without the use of vaccines. Prophylactic immunization by vaccines in certain diseases, such as small-pox and typhoid, stood upon firm ground. Curative immunization was on a less secure footing, and much of the vaccine therapy of the present day was purely empirical.

#### Clinical Cases.

Mr. E. R. FLINT (Leeds) showed a case of cervical rib in a schoolmistress, aged 23, who had complained of pain during the previous eighteen months in the whole limb occurring towards the end of the day, with neuralgic pain shooting into the inner side of the right arm and hand and some wasting of the intrinsic muscles of the hand. The rib was attached to the thoracic rib in front, and the subclavian artery and inner part of the plexus lay in front of the lower part of the cervical rib. Great improvement had followed its removal one month ago. There was also a small cervical rib on the left side which did not produce symptoms.

Dr. WILLIAM MACADAM (Leeds) demonstrated a case of intermittent hydrarthrosis. A woman, aged 25, otherwise healthy, had suffered from periodic attacks of synovial effusion of the ankle- and knee-joints, lasting three or four days, and preceded by loss of appetite, dyspepsia, and polyuria. There were also attacks of angioneurotic oedema occurring at times apart from those of the joint swellings and affecting one side of the face, the hand, and the subcutaneous tissues of the lower limbs. During a year's arsenical treatment there had been one attack of a localized erythema of the lower limbs, but no recurrence of the synovial effusions.

Dr. J. STEWART (Leeds) showed a female patient from whom he had removed two stones from the common duct during an attack of haemorrhagic pancreatitis two years ago.

#### MULE-SPINNER'S CANCER.

At a meeting of the Manchester Pathological Society held at the Manchester University on December 8th, with Dr. E. M. BROCKBANK, the President, in the chair, Dr. JAMES ROBERTSON (M.O.H. Darwen) read a paper on "Mule-spinner's cancer."

Dr. Robertson recalled that since 1920 the attention of those engaged in cotton-spinning had been directed towards scrotal cancer because of its increased incidence among mule-spinners. Anxiety among employers had also arisen since the judgement given in 1922 in a Lancashire county court that, upon the evidence laid before it, this disease arose out of and in course of the workman's employment. The evidence was to the effect that the mineral oil used to lubricate the spinning-mule was thrown off by the rotating spindles on to the circular steel rod known as the faller shaft and on to the spinner's overalls. The friction of the shaft on the scrotum as the man leant over it, together with the irritation of the oil, were stated to be the causes of the disease. The question first arrested

Dr. Robertson's attention in 1923 in the course of official visits to cotton-mills. Observation led him to doubt the prevailing opinion as to the cause of mule-spinner's cancer. He began investigations which led him to express these doubts in his annual report for that year, and to advance a counter-opinion. The starting-point of his inquiry was the article by Southam and Wilson.<sup>1</sup> After describing the mechanism of the mule and its faller shaft, and the process of oiling, and his experiments to determine the duration and extent of oil spray from the spindles, Dr. Robertson adduced evidence showing that no mineral oil reached the workman's overall from the spindles or shaft, and that no friction or pressure from the shaft was exerted on the scrotum; from this he concluded that these could not be the cause of spinner's scrotal cancer. Further investigation convinced him, moreover, that none of the oil absorbed from the workshop floor by the overall reached the scrotum under ordinary working conditions, and that mineral oil could not therefore be a factor in the causation of this disease. While the dirty scrotum, the mineral oil, and the movements required of the workmen had not changed since 1880, this form of cancer had only lately become serious, and he looked about for some recent factor or factors acting upon the scrotum and on a definite part of it. Until 1905 cotton-spinners wore soft white overalls of fustian, free from chemicals. But about that time blue overalls of a hard cheap material began to be used and gradually displaced the others. These stiff blue overalls were worn next the skin and held up by cloth straps over the shoulders. In the movement of piecing together broken ends of thread the pull of the overall, with its rough seam at the fork, caused slight pressure and friction on the exact points of the scrotum where epithelioma was usually found. Dr. Robertson accordingly suggested that these rapid intermittent frictions, some 240 in an hour, acting upon an unprotected and dirty scrotum, and in the presence of an aniline dye, were the cause of the disease, the friction and pressure being aggravated by the use of an inelastic brace. In support of this view he had ascertained that wool-spinners, who scarcely ever suffered from this disease, wore their overalls over a soft undergarment, and that the French cotton-spinners of Lille (among whom such cases were unknown, although they worked under the same conditions) wore similar overalls, but kept them up with waist-belts. Thus neither in the wool-spinner nor in the Lille cotton-spinner was there any friction of the overall upon the bare scrotum when the workman leant over the shaft to piece his broken thread. Although the Lancashire cotton-spinner worked in his naked feet on the oily floor of the spinning-room, yet he never suffered from cancer of the foot, or even sores on the sole.

In short, Dr. Robertson's conclusion was that this disease was not due to conditions in the mill, but to the friction (*plus* the scrotal state) resulting from the shoulder pull upon an inelastic brace, causing the fork of the overall to rub against the skin. Out of 29 cases seen by him who had been operated upon, 28 wore blue overalls. His experimental work convinced him that the spinner should wear a white fustian overall supported by an elastic brace, or if he wore a hard overall should have next his skin a short undergarment of soft material, and should wear an elastic brace or a waist-belt. The worker must also keep his scrotum clean. Further, since these investigations had proved that all the oil found on overalls came from the floor, the spinning-room floor ought to be washed at least every two years.

In the discussion which followed, Dr. BROCKBANK remarked on the absence of scrotal cancer in the wool-spinning industry.

Mr. A. H. SOUTHAM said that the skin of the sole of the foot was very different from the scrotal skin, and was not so liable to cancer. He had seen two cases of epithelioma of the air passages (one of the tonsil and one in the larynx) combined with scrotal cancer. He suggested that scrotal friction might also be present in other occupations, such as coal-heavers. Yet these people were not liable to scrotal cancer.

<sup>1</sup> BRITISH MEDICAL JOURNAL, November 16th, 1922.

Dr. PROSSER WHITE had noticed keratosis of the skin and "irritative papules" of the forearm in mule-spinners who had been away from their work for as much as two years. He did not advocate the radical removal of the inguinal glands in cases of scrotal cancer, as he regarded this condition as a localized one, and he cited 33 cases in which removal of the inguinal glands had been followed by bad results.

Mr. J. MORLEY mentioned the case of a man who for thirty years performed only unskilled labour in the mill, but who had epitheliomata of the scrotum, face, and arm. There was no question of local friction in this case. He had seen tar workers with keratotic papules of the skin where they had been splashed. He asked if the scrotum and penis were soiled with oil by the hands during micturition. He strongly advocated the removal of the inguinal glands in cases of scrotal cancer, which, he said, always resulted in glandular metastases. He emphasized the difficulty of this operation and the bad results which might accrue, especially if the field of operation were soiled by lymph from cut vessels.

Dr. POWELL WHITE cited cases of scrotal cancer occurring years after the cessation of work. Dr. I. SAVATARD showed lantern slides of a case—a mule-spinner with a keratotic nodule of the scrotum and epitheliomata of the face and arm—and drew attention to the relationship between epithelioma and the conditions of xeroderma and ichthyosis of the skin. He suggested that the general atmospheric conditions prevailing in Lancashire had something to do with the incidence of skin cancer.

Dr. VEITCH CLARKE congratulated Dr. Robertson on his "field work." He mentioned the high incidence of cancer among chemical workers—where there was no local friction. He suggested that a specific reaction might take place between mineral oils and the sebaceous oil of the skin in bringing about the onset of cancer of the scrotum.

Dr. ROBERTSON, in reply, pointed out that a wool-spinner wore an undergarment, hence there was much greater protection. Coal-heavers wore soft trousers, and often no braces. All workers' hands were thoroughly cleaned after oiling the machines. If oil were on the scrotum, he thought that the incidence of cancer might be even greater. The late cases of scrotal cancer might be those that would occur in the ordinary way, apart from occupation. Chemical workers did not need to be as careful with their hands, hence contamination was easier. He strongly advocated the abolition of braces and their replacement by belts in mule-spinners.

### SURGICAL DIATHERMY IN CANCER.

At a meeting of the Manchester Medical Society on December 1st, Dr. F. CRAVEN MOORE in the chair, Mr. H. H. RAYNER read a paper on surgical diathermy in the treatment of cancer.

Mr. Rayner described the principle and technique of surgical diathermy, and dealt with its employment in the treatment of malignant disease of the skin and of the breast. Cases of buccal carcinoma were not included because the value of the method in these was now widely recognized. The advantage of diathermy in the treatment of cancer was threefold. It eliminated the possibility of implantation of living cancer cells in the operation wound; this reduced the liability to local recurrence after treatment. It sealed divided lymphatic channels in the open wound, which probably diminished the chances of the rapid development of distant metastases after operation. His experience in the removal by diathermy of massive breast cancer, as a palliative measure, led him to suggest that the ordinary cutting operation in these advanced cases was responsible, in some of them, for the rapid outbreak of metastases, and that such a sequel was less likely after diathermic removal. The third advantage was that the sterilization of the wound produced by the intense heat eliminated the chance of serious sepsis. This property made it possible to employ diathermy without fear of septic infection for the removal of foul ulcerating growths of the skin or breast, or growths about the anal margin, or in other positions prone to infection. The slough produced by the heat of the current provided a reliable protective

barrier during the time that an ordinary open wound was most prone to infection—before the formation of a floor of granulative tissue. The cases quoted included fourteen cases of carcinoma of the skin—eight cases of rodent ulcer, two of lupus epithelioma, four of ordinary skin epithelioma, two involving the skin of the perineum and invading the anal canal. All these had been treated by diathermic excision within the past three years; there had been no instance of local recurrence in any of these. One of the patients with anal epithelioma died of internal metastases two years after operation without local recurrence or trouble. This man had, at the time of operation, an extensive and foul fungating growth invading one lateral wall of the anal canal—he had been sent into hospital for colostomy. Nearly all the rodent ulcer cases and the two lupus epithelioma cases were extensive and had been previously treated by x rays, radium, or operative excision, sometimes by all of these methods. Ten cases of massive and inoperable breast carcinoma had been submitted to diathermic removal of the breast as a palliative measure; no attempt was made to remove the axillary glands in these. Of these patients three died within eight to fifteen months of the operation, while seven were alive at periods ranging from one to two and a quarter years after the operation. Eight of these ten were considered to have received substantial benefit from the operation, most of them being able to lead ordinary lives for at least a year after operation. The type of case for which diathermic removal was advocated was that presenting a massive enlargement of the entire breast with ulceration, or impending ulceration of the skin, and unaccompanied by clear evidence of metastases except in the axillary glands. Lantern slides to illustrate the results of treatment in several of the skin carcinoma cases were shown, and some also to indicate the types of mammary cancer considered suitable for diathermic removal.

### Habit Formation in Blood Vessels of the Skin.

Dr. P. B. MUMFORD, in a paper on this subject, said that the blood vessels of the skin, by constant usage of their power of contractility and dilatation, might acquire a habit of responding to lessened stimuli. Such stimuli might be external or internal in origin. They might be chemical, thermal, mechanical, or nervous in type, and the development of hypersensitivity to one form of stimulation was not necessarily specific for that form of stimulation only. The continual demand on capacity for rapid contraction or dilatation induced a markedly labile condition of the arterioles and capillaries affected. Dr. Mumford next showed that a distinction must be drawn between continuous and intermittent demand for dilatation, as the former often appeared to induce a paralytic change. Both "specific" and "non-specific" sensitization of the skin to external stimuli occurred. The vascular habit might be produced as a remedial measure in conditions such as pernio.

### SURGICAL ASPECTS OF JAUNDICE.

At a meeting of the Nottingham Medico-Chirurgical Society on November 10th, with the President, Dr. J. C. BUCKLEY, in the chair, Mr. A. H. BURGESS, surgeon to the Manchester Royal Infirmary, gave a lecture on the surgical aspects of jaundice.

Mr. Burgess, after defining jaundice, said that owing to the work of van den Bergh there was now recognized a "latent" jaundice in which the bile pigment in the blood was increased above the normal, but not sufficiently to overcome the kidney threshold and appear in the urine. He briefly described the van den Bergh test and the different results—immediate, delayed, and biphasic—explaining that the result depended upon whether the pigment had or had not passed through the liver. Mr. Burgess further discussed the work of Mann and Aschoff proving that the bile pigments were not formed in the liver, and the part played in their formation by the reticulo-cellular system, principally in the bone marrow and spleen, and only to a very small extent in the liver.

He then mentioned the different varieties of jaundice and the diagnostic significance of the van den Bergh test in obstructive and acholic jaundice. In dealing with obstructive jaundice he stated that, while deep jaundice of short duration was not a severe surgical handicap, in long-standing cases it made the patient a very bad surgical risk, owing to liability to haemorrhage and other complications, such as an increase in bile secretion with a decrease in its quality. He mentioned the various measures to overcome these risks, such as blood transfusion and the intravenous injection of calcium chloride, and entered a strong plea for a two-stage operation with a minimal interference in very bad cases. He pointed out that in chronic jaundice, for all practical purposes, the diagnosis lay between that of common duct obstruction due to stone and that due to cancer of the head of the pancreas. He stressed the importance of the slightest diminution, however temporary, of the jaundice as deciding in favour of stone obstruction, and discussed Courvoisier's law and the importance of a distended gall bladder in the differential diagnosis of these conditions. He mentioned the usefulness of cholecystogastrostomy and various drainage operations in malignant and other forms of bile obstruction, and referred to the value of splenectomy in non-obstructive jaundice.

### ENCEPHALITIC NYSTAGMUS.

A CLINICAL meeting of the Devon and Exeter Medical-Chirurgical Society was held at the Royal Devon and Exeter Hospital on November 18th, the President, Mr. R. WORTHINGTON, in the chair.

Dr. W. GORDON showed a case of encephalitis with nystagmus in a boy aged 9. There was a history of sudden onset with headache and pain in the back of the neck. On admission to hospital he looked dazed, but answered questions intelligently. The cerebro-spinal fluid redness Fehling's solution markedly. The boy developed coarse nystagmus and paresis of the right arm. The symptoms were beginning to clear up. Dr. Gordon stated that inco-ordination of the eye was now associated with encephalitis lethargica. In his case the possibility of infantile paralysis had been suggested, but the symptoms cleared up rapidly, whereas in true infantile paralysis this was not usual. There was, as a rule, more destruction of cells in infantile paralysis, whereas the injury might be transient in encephalitis.

Dr. HERBON DATE said that Dr. Gordon's experience was somewhat opposed to his own; in school investigation during outbreaks it was by no means uncommon to find the ambulatory type of infantile paralysis. As a point in the differential diagnosis, the eye inco-ordination was certainly new to him. Dr. EAGER recounted his experience of patients who showed post-encephalitic sequelae with paraplegia, and evidence of permanent damage to the nerve cells. He recommended hyoscine in treatment.

Dr. GORDON, replying, said that he had dealt only with immediate effects, and not with sequelae; severe localizing symptoms of a stationary type at the onset were more likely to indicate infantile paralysis, whereas the transient and diverse symptoms occurred more frequently in encephalitis. He had not had any experience of hyoscine, but he had found belladonna useful. As regards treatment, injections of potassium permanganate by rectum had been given in this case. Another form of treatment advocated was that of Letters, who produced an aseptic abscess on some part of the body, such as the thigh, using turpentine as the local irritant, the idea being to create leucocytosis.

### Tuberculous Pyonephrosis.

Mr. WAYLAND SMITH and Dr. ACHESON showed a married woman, aged 32, with tuberculous pyonephrosis. She was first examined in March, 1925, having had pain on micturition for ten months. There was a hard mass on the right side of the abdomen. She was cystoscoped and pus was found coming from the right ureter; tubercle bacilli were present. Nephrectomy was performed. The patient's weight in April, 1925, was 7 st. The after-treatment at her home, which was in one of the poorest quarters of Exeter, was conducted by Dr. Acheson. Her weight now

was 8 st. 7 lb., and a catheter specimen taken last August showed a few pus cells, no organisms or tubercle bacilli, and no growth was obtained on culture.

Mr. A. L. CANDLE commented on the success of the operation in spite of the presence of advanced open tuberculosis; it had apparently resulted in complete recovery.

Mr. WAYLAND SMITH emphasized the value of the after-treatment; carried on in spite of the most unfavourable surroundings and structural obstacles, open-air treatment had been maintained throughout convalescence.

Dr. ACHESON gave a short account of the case and of the great difficulties he had encountered in providing the requisite treatment. Having, with considerable trouble, obtained an area of sun-exposed roof, and established the patient there for some weeks with great benefit, there was a subsequent and most disappointing eviction, and now he was doing as well as he could for the woman in one room shared with her husband and child.

### Fracture of the Acetabulum.

Mr. WAYLAND SMITH showed a man, aged 63, with a fracture of the acetabulum caused by a fall from a scaffold in June, 1925, the patient landing on his left hip and buttock. Two months later he complained of pain in the knee and back of the thigh when he tried to move it. There was marked wasting of the left buttock and tenderness along the line of the sciatic nerve. X rays showed a fracture of the left acetabulum with a partial dislocation of the head of the femur into the pelvis. The fifth lumbar vertebra was also displaced and spondylitis deformans was present. The patient was treated by massage, radiant heat, and exercise. There was now flexion to the extent of 30 degrees at the hip, but the patient could bend the hip to a right angle, and walk with the aid of a stick. The interest of the case lay in the unusual type of fracture, and the subsequent return of function, although the diagnosis was only made two months after the fracture.

### JAMES MACKENZIE INSTITUTE.

#### Acidosis in Children.

Dr. H. CHARLES CAMERON (London), on November 16th, read a paper on "Some forms of acidosis in children," limiting his remarks to periodic or cyclical vomiting and allied conditions. He reviewed recent advances in knowledge of the biochemistry of the blood bearing on the subject, especially the factors involved in regulation of pH and in the formation of the ketone bodies. He showed that in the ketosis of cyclical vomiting the pH of the blood was unaltered though alkaline reserve was diminished and pulmonary ventilation increased. The acidosis was, therefore, in the majority of cases a compensated one, and the symptoms were due to the effort of the body in keeping the hydrogen ion concentration constant. Once this compensatory mechanism failed the condition became one of extreme danger, and the symptoms were referable to the alteration in pH. He emphasized the importance of intake of a correct carbohydrate-fat ratio showing that excess of fats resulted experimentally in ketosis, while carbohydrates had an antiketogenic action. Comparatively little biochemical research had been done in connexion with cyclical vomiting, but Wilson Levine and Rivkin had made observations which suggested that the subjects of this condition assimilated fats with greater readiness than the normal child. Turning from the biochemical aspects of the matter, the lecturer gave a vivid picture of the type of child in whom cyclical vomiting occurred—nervous, amyotonic, with unstable peripheral circulation, and showed that minor degrees of periodic illness, not reaching the level of severe vomiting, were characteristic of these children. He dealt fully with the management of such children, showing the value of diminishing the ketogenic elements in diet and of maintaining the alkaline reserve. He specially urged the importance of avoiding those environmental factors which experience had shown to be liable to precipitate attacks—for example, overexertion, excitement, febrile affections. Dr. Cameron concluded by emphasizing the importance of careful study of the early symptoms and constitutional peculiarities of the subjects of cyclic vomiting.

## Reviews.

### A TEXTBOOK OF SCHOOL HYGIENE.

By the publication of his book *The Fundamentals of School Health* Dr. JAMES KERR, formerly school medical officer for London, has filled a gap in medical literature. Many excellent books on school hygiene, among them two by Dr. Kerr, have been written, and some of them have gone through several editions; they have stressed some one or other side of school work with which the author has been most familiar. The administrator in school medical affairs has rarely had an equal familiarity with the purely medical, or what is commonly called the "clinical," side, while those most engaged in the clinical work have been less cognizant of, or perhaps less interested in, the administrative side. So that it has come about that until now there has been no work on school hygiene in any way comparable to the admirable "systems of medicine" which we have had for generations down to Allbutt's and Osler's. But the deficiency has been made good. Dr. Kerr has had the good fortune to be both clinician and administrator. He was a clinician first, and throughout a long and distinguished career of administrative work of the greatest responsibility, both in Bradford and in London, he has never lost his enthusiasm for clinical work. He has remained a clinician. Accordingly, his book exhibits in a high degree the outlook of the accomplished administrator inspired by clinical insight.

It is no easy matter to give a fair impression of a volume of this order within the compass of a review. It contains nearly nine hundred well filled pages, and is obviously the result of patient recording and checking of accumulated facts during many years. Dr. Kerr has in fact been concerned with school medicine from the beginning. He was the pioneer of school medical work in Bradford, and again in London. The great organization that now exists in these two cities and in every part of the country came into being contemporaneously with his work. Few have any conception of its vastness, even if attention is confined to London. It is all based upon beginnings that were venturesome, or so thought at the time, though they have proved sound. Dr. Kerr's original ventures were planned with rare good sense, so that there has been little "reconstruction," but always further growth on the original lines of the conception. In writing this volume Dr. Kerr has gathered up his experience and followed it to the present-day development of an established system of health culture the like of which has never before been seen. Such an achievement is as rare as the privilege of seeing ambitions fructify in the fashion that he has seen his.

The book is a library. No side of school work is forgotten. Each section is dealt with, whether it be heredity, growth, physique, play, nutrition; or the more medical conditions of dental hygiene, nutritional diseases, and malnutrition as shown in crippling effects; or the educational side as exemplified in the conditions of elementary schools, of special schools, and the desiderata of sunlight, good artificial light, sanitation, facilities for washing, warming, and the choice of building sites. We have the whole gamut of clinical entities such as speech defects, eye, nose, and ear defects, and mental disabilities and their numerous correlations. All these are effectively dealt with and in well balanced style. The achievements of the growing company of workers in school medicine are liberally recognized. References abound to original literature. Withal the book is intensely practical. It is intended for the use of workers in the field, in the schools, for their assistance in their daily endeavour to secure better and still better conditions for the children.

Criticism of minutiae would be hypercriticism. But in a second edition—and we judge there will certainly be an early demand for one—we should welcome a fuller index of facts, a separate index of authors, possibly also an

extended bibliography, giving titles of papers referred to as well as of publications in which they appeared. Such additions would assist research workers. They would take some additional space, but some saving might be made by the omission of a few of the less necessary illustrations.

Every local education authority in the country might well provide its medical staff with a copy of this work; and it is likely that the technical staff, besides the medical staff, would be diligent readers of it.

### DISORDERS OF METABOLISM.

PROFESSOR ACHARD is so much in earnest about the special argument of his book *Troubles des Echanges Nutritifs* that he has been at pains to introduce some hint of it into the title. In translating this as "Disorders of metabolism" we therefore do the author something less than justice, though, perhaps, we more adequately describe the scope of the book than would a literal translation. Professor Achard insists that the time has arrived in the evolution of medical thought when abnormal conditions should be described no longer by the symptom-complex in evidence, but rather in terms of the departure from complete physiological orderliness which is involved. With such an aspiration few will quarrel, but they will perceive that its logical pursuit in a comprehensive textbook demands a dogmatic physiology and a very definite conception of what a well ordered animal is.

The author defines the living organism as a system in equilibrium with its environment. Physical chemists will find occasion for pause, but the definition will serve, and for the present purpose it serves very well, for it gives to metabolism a special significance which Professor Achard uses to good purpose. The nutritive exchanges comprise the whole traffic with the outer world which is involved in the maintenance of this equilibrium, and find expression in physical or chemical balance sheets of intake and output. In the case of the organism with which medicine has particular concern the system is at once complicated and simplified by the presence of a stabilized environment in the form of a circulating fluid, and so the equilibria between blood and the exterior, on the one hand, and between blood and the tissues, on the other, must occupy the chief attention of students of metabolism. Whatever prejudicial alteration occurs in the external environment, whatever is responsible for defective absorption or impaired exchange, whatever leads to imperfect utilization of nutritive materials within the tissues or impedes the necessary disposal of waste products will be betrayed in the balance sheets as a disturbance of the nutritive exchanges—a disorder of metabolism. Among the defects of the environment there are considered natural and artificial changes in the gaseous atmosphere leading to disturbances in the respiratory exchange and the chain of readjustments, notably in the electrolyte balance of the blood, which these set in motion. Again, an unbalanced diet, lack of certain minerals, vitamins, or efficient proteins are defects in the same category which will have consequences uncovered in the nutritive exchanges. Disorders of the circulation, be their origin pulmonary, cardiac, or nephritic, errors of utilization, absorption, or excretion, whatever be the primary lesion, failure of co-ordination by nervous, vascular, or endocrine agencies, all invade the field of nutrition through the modifications which they impose on the equilibria of the blood. The author takes a catholic view of nutrition. He demands much of physiology, and sometimes we find him quoting confidently relations which are yet unproven and straining a little beyond the certitudes of knowledge, filling in detail where the eye has not yet been focused.

The book appears in two volumes for the suitable reason that it is too bulky to be constrained conveniently within one cover. The first and larger volume deals with gaseous, aqueous, and mineral exchanges, and each chapter involves a physiological introduction, a pathological discussion, and a consideration of the therapeutics in the disorders

*Fundamentals of School Health.* By James Kerr, M.A., M.D., Consulting Medical Officer, London County Council. London: Allen and Unwin Ltd. 1926. (Roy. 8vo, pp. xvi + 853; 163 figures.)

*Troubles des Echanges Nutritifs.* Par Ch. Achard. Paris: Masson et Cie. 1926. (Roy. 8vo: Vol. I, pp. vi + 695; 107 figures. Vol. II, pp. 625; 60 figures. 110 fr. the two volumes.)

uncovered. In the second volume, following the same plan, there come under review the nutritive exchanges of carbohydrate, fat, protein, urea, uric acid, ketone bodies, and other intermediate metabolic products.

The argument upon which the diagnosis rests is carried over into the therapeutics. The problem is to re-establish a normal equilibrium either by removal of the cause of disturbance or, if this be impracticable, by such modification or artificial compensation of the environment as will tend to reimpose the normal balance. To this environmental therapeutics the author brings many inventions of man to assist. Control of diet naturally takes prominent place, and it is pleasant to record that so enthusiastic a dietetician makes the caution that since the intention of a régime is that it should be followed, it should therefore be followable and of such sort as to minimize the inconvenience and distaste inevitable in any disciplining of the appetites.

The form of presentation which has been described involves the appearance of some specific disorders in several chapters, so that the whole story of a particular disease cannot be found in one place. But what has been done has been done with intent, and the path of the desultory and of the purposeful reader is rendered easier by an ample index. Professor Achard deserves our thanks for a sincere attempt to bring closer the ways of the clinician and the ways of the physiologist. He merits thanks also for providing a book which, apart from its special argument, is a sound review of the state of knowledge in the field of normal and disordered metabolism. The price fixed by the publishers is not extravagant.

#### DISEASES OF THE EAR.

It is nearly twenty years since the late Mr. Hunter Tod published a book on *Diseases of the Ear*.<sup>3</sup> It was of moderate size and gave in plain language a simple and adequate account of the subject, and its excellence was proved by the large circulation it soon acquired, for it was reprinted three times. The untimely death of Mr. Tod, a source of profound sorrow to numerous friends and colleagues, prevented him from producing a second edition, and Dr. Cathcart has undertaken this task; he has retained the general style and appearance of the original edition, but, although he has endeavoured to make it as he believes Mr. Tod would have made it, the long interval has rendered necessary so many changes and additions that this effort has not, and could not from its very nature, have been entirely successful. It is a commonplace that it is more difficult to write a comparatively small book of this kind than an exhaustive treatise, because it is so difficult to know what should be left out. Dr. Cathcart, in trying to say what he believes Mr. Tod would have said, shows an inclination to touch on some fresh matters so lightly that the information is insufficient, though everything new has been introduced in a sympathetic and understanding spirit. Apart from this criticism of a feature which was perhaps unavoidable, there can be nothing but praise for the care and accuracy with which the new edition has been compiled, and it remains a safe and rational guide to the practitioner and student for all conditions commonly encountered. The illustrations are fairly numerous and suffice for their purpose, but a few are crude and in an artistic sense fall below the standard of the book, both in its text and general style. The new edition should retain the popularity of the former, whilst there will be many grateful to Dr. Cathcart for this graceful tribute to the memory of Hunter Tod.

*Politzer's Text-book of Diseases of the Ear*<sup>4</sup> has long been the sheet-anchor of every serious student of otology, and must be in the possession of every aural surgeon for

reference. There is no other book which gives so broad and comprehensive a survey of otology, whilst at the same time every detail relating to anatomy, physiology, and pathology is studied with minute care. The sixth edition will therefore be welcome, but the responsibility for any changes now rests with Dr. BALLIN, who translated the last two editions at the request of the late Professor Politzer. These changes are not actually very numerous, but they are more important than a casual inspection might suggest, for the editor gives very few references to his sources of information, whilst the original references of Politzer are retained in almost precisely their previous form. A certain amount of obsolete matter has been omitted to make room for these alterations, and the editor might have been even more drastic, but it has to be remembered that the work is Politzer's, and that for many years it will remain the classical work on otology, based on sure and unchanging foundations. The editor therefore has exercised good judgement in restraining the temptation to alter the original, whilst at the same time he has actually omitted nothing of essential importance that has been produced during the last fifteen or sixteen years. This refers chiefly to the labyrinth, and there is a sufficient account of the various operations that have been proposed, most of which only differ in minute details, the objective for the most part being the same. The prognosis of meningitis is possibly not quite so gloomy now as it was in 1909, and in this part more recent observations might have been mentioned. The main consideration, however, is that this great work is still preserved almost intact, the attempt to give it a modern setting being in reality almost unnecessary. The general style of the volume is almost unaltered and the familiar illustrations, so many of which were from anatomical and pathological specimens in the author's collection, are retained, and are by no means the least instructive part of the book.

Dr. CATHEART introduces his book on *The Treatment of Chronic Deafness by the Electrophonoid Method of Zünd-Burguet*<sup>5</sup> with a robust but unconvincing defence of empiricism. It is a commonplace that much medical treatment is empirical, but this is a misfortune and calls for apology rather than defence. The fact that the treatment recommended in this book is empirical in no way discredits it, but how much better the author and reader would feel if it had a sound scientific basis. After calling attention in this manner to a weak point in his thesis without any real necessity, the author then discusses the prevention of deafness, the best method of removing adenoids, and a variety of other matters on which he holds strong opinions. This all makes interesting reading, but it is not apposite, and the reader is half-way through the book before arriving at the "osses." The second half of the book begins with an historical note on methods of auditory re-education. There follows a careful description of the apparatus of Zünd-Burguet and the manner of employing it. Finally there are records of a hundred cases of deafness, showing that sixty-eight improved. It is not possible to tell from any tests made beforehand whether the treatment will be successful, and it is necessary to give twelve sittings to ascertain this. The author says of this, "There is a factor in deafness as yet unrecognized, the presence of which—or it may be the absence of which—determines the result." In the cases treated the pathological lesions were very varied, and this suggests that the factor to which the author refers may be a functional one, for a functional defect is often added to the initial lesion in the hard of hearing. It must be obvious to anyone dealing with the deaf or partially deaf that the "malady of not marking" is only too frequent, and this may explain the possibility of re-educating some of them. The most remarkable claim is the relief from tinnitus, a condition of which such patients frequently complain more than of their deafness. It is quite clear that the method to which the author has devoted much time and study is worthy of serious attention.

<sup>3</sup> *Hunter Tod's Diseases of the Ear*. Revised and largely rewritten by George C. Cathcart, M.A., M.D. Second edition. Oxford Medical Publications. London: Milford, Oxford University Press. 1926. (Cr. 8vo, pp. xiv + 333; 87 figures, 4 plates. 10s. 6d. net.)

## TECHNICAL EDUCATION FOR INDIANS.

*Technical Education*\* is written for Indians, by the Principal of the School of Chemical Technology, Calcutta, as a guide to careers in the Indian public services and in commerce and industry. In a foreword Sir Willoughby Carey describes it as an excellent effort to clear up much confusion of thought which still exists as to the meaning of technical education in Bengal and its uses in assisting to reduce unemployment amongst the educated middle-class young men of the province.

Mr. GHOSH, the author of the book, goes further, and endeavours to show how technical education is a means of providing permanent and profitable employment, not only for the educated middle class, but also for the artisan class, the agriculturist, and the Anglo-Indian. In an opening chapter on the evolution of technical education in India he emphasizes the failure of previous attempts to introduce this form of education amongst the natives of India, chiefly because an erroneous distinction was made between technical and industrial education. Indian youths have been mistaken in persuading themselves to believe that the attainment of literary qualifications carried chances of employment, whereas their best chances are in becoming educated in agricultural and technical chemical sciences and in the crafts. From this point of view the author outlines a scheme of technical education which is suitable for the artisan or any other class, and which will give a prospect of earning a living by independent professional or technical work. By this he means that each caste or class should continue its traditional occupation, but should be trained to a higher degree of efficiency in it in the light of modern science. He remarks, for example, that the agricultural caste must remain agricultural in spite of a higher education. Much space is devoted to the subject of chemistry, especially in connexion with agriculture, medical research, and pharmacology, in all of which branches of knowledge technological education affords prospects of employment to the Indian student.

Mr. Ghosh takes long views and wide views of the subject, and he writes with the object of rousing his fellow countrymen from that lethargy which disinclines them to accept manual work and leads to a false sense of dignity in office and administrative work requiring literary qualifications. More than half of the book consists of twenty-six appendices of information regarding the regulations for admissions to, pay and appointments in, and latest particulars of, all-India and provincial public services, and of careers in commerce, trade, and industry. A book of this kind should prove of much value to Indians, and we heartily wish its author success in his attempt to deal with the problems of unrest and unemployment among his fellow countrymen, and to provide them with what he calls an introduction to health, wealth, and happiness.

## NOTES ON BOOKS.

DR. J. F. HALLS DALLY's manual on *High Blood Pressure: Its Variations and Control*,<sup>†</sup> which was reviewed in our columns three years ago (1923, ii, 1101), has now been revised and enlarged in the second edition, which costs rather more, and has been somewhat delayed by, among other causes, destruction of the type. The work has been kept thoroughly up to date—for example, Major's work on hepatic extract in reducing high blood pressure is recorded, but it does not appear that the author has employed it. An investigation of the blood pressure in the two arms in pulmonary tuberculosis does not support Dr. H. J. Cyriax's conclusions as to the significance of differences between the two sides. There are references to the late Sir Clifford Allbutt's posthumous book (1925), to the discussions at the Annual Meeting of the British Medical Association at Bath and at the Royal Society of Medicine on hyperpiesia, and Dr. R. Fortescue Fox has provided a section on the treatment by baths and waters. This edition preserves the useful character of the manual.

\* *Technical Education*. By J. C. Ghosh, B.Sc. Manch., F.C.S. Calcutta: Thacker, Spink and Co. 1926. (Gr. 8vo, pp. ix + 316. Rs. 4.8 or 8s. net.)

† *High Blood Pressure: Its Variations and Control*. A Manual for Practitioners. By J. F. Halls Dally, M.A., M.D., B.Chir. Cantab., M.R.C.P. Lond. Second edition. London: W. Halcemann (Medical Books), Ltd. 1926. (Demy 8vo, pp. xvi + 196; 20 figures. 12s. 6d. net.)

Even in the early days of training the mental nurse is liable to be faced with situations which demand prompt and efficient action. It is therefore desirable that she should be supplied at the outset of her career with a guide indicating the rules to be observed in dealing with patients and how to react to emergencies. Such information is supplied in Dr. RICHARD KAGER's compact little volume on *Hints to Probationer Nurses in Mental Hospitals*,<sup>‡</sup> the second edition of which has now been issued. It is a book which the probationer will do well to obtain, and, as the author advises, to read over frequently during the first few months of her training. The first part deals with rules, emergencies, fire, ward duties, homicidal patients, and "escapes"; the second provides a brief introduction to psychology which will help the nurse to understand the more detailed account of the mind given in the larger nursing manuals.

A recent review in these columns reported the reappearance of Dr. OTTO FÜRTH's book on problems of physiological and pathological chemistry<sup>§</sup> in a new guise. From the travails of re-editing the "problems" had emerged, cast in a wider mould, as a textbook. Only the first part of the first volume was then in our hands, and we did not hesitate to commend it, finding that the spirit of the parent volume remained in the more comprehensive treatment which merited the change of title. This section dealt with the organic chemistry of the substances of living origin and with the chemical characterization of the blood. Of the second part it need only be said that it deals in a similar manner with the mechanism of the muscle process, with the chemistry of the brain, connective tissue, and bone, and with the secretory function of the liver, kidney, mammary gland, and thymus. All is adequate, up to date, judicious, and alive. The first volume will be completed by a section on the chemistry of the organs of internal secretion, and a promise is made that this will be followed by a second volume devoted to the chemistry of metabolism.

Dr. PIERRE LEREBoullet's little work on influenza,<sup>||</sup> which forms the latest addition to the series entitled "Les actualités médicales," is based on his experience of the disease during the pandemic of 1918-19 and of sporadic cases since. The book has five parts, devoted respectively to epidemiology and bacteriology, symptoms and complications, morbid anatomy, diagnosis, and prophylaxis and treatment. The bibliography consists of references to French literature almost exclusively, but the work of some British and American observers receives recognition in the text. The book may be recommended as being a lucid and practical exposition by a leading French physician.

## ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the committee forty cases were considered, and £440 was voted to thirty-one applicants. The following is a summary of some of the cases relieved.

Daughter, aged 66, of L.R.C.S. who died in 1883. She used to make about 25s. a week by teaching, but since an attack of influenza two years ago she had been unable to work. A friend left her £42 a year, and she receives £16 from a relative; her rent is 6s. a week. Voted £18 in twelve monthly instalments.

Widow, aged 68, of L.R.C.P. was a clerk until Christmas, 1924, but has found it very difficult to get a post since. Her late husband was an annuitant of the Fund. The applicant receives £52 from the rent of a house, but has to pay interest on mortgage and ground rent and repairs. Voted £5 while seeking employment.

Daughter, aged 63, of M.D. who died in 1913. She has maintained herself by taking temporary posts as a clerk, but owing to recent illness has asked the Fund for further assistance. She has an annuity of £40. Rent and gas amount to £44 per annum. Private typewriting and clerical work brought her in about £78. Relieved twice £17 10s.; voted £12 in twelve monthly instalments.

Daughters, aged 64 and 66, of M.R.O.S. who practised in Wales and died in 1873. They live in a two-roomed hut for which they pay £1 per annum ground rent. One has the R.U.K.A. annuity of £26; they made £5 from poultry, and friends gave £7. Relieved ten times jointly £154. Last year voted £24 each in monthly instalments, which was renewed.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., C.B., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

# British Medical Journal.

SATURDAY, DECEMBER 18TH, 1926.

## EPSOM COLLEGE.

Education on right lines is an almost indispensable precedent of success in life; it is also an essential condition of the progress of any science which requires from those engaged in it an unselfish outlook, together with patient and honest work. The medical profession as a whole is, therefore, under a double obligation to support the only public school which has as a primary aim the provision of special facilities for the sons of medical practitioners to receive such training as will enable them to take up the study and practice of modern medicine. Epsom College, as we have often had occasion to mention, is leaving no stone unturned to ensure that the first stages of the long medical curriculum should be adequate in the instruction given, and in the inculcation of those ideals of scientific discrimination without which diagnosis is impossible and treatment becomes empirical. We referred on July 31st (p. 218) to the opening of the new chemical block, with its unsurpassed facilities for teaching this important preliminary in the medical course. The provision for instruction in biology has also received the fullest possible attention.

Something more is still required, however, since Epsom College should furnish a similarly high standard in all respects. We therefore invite special attention to the appeal of Dr. Raymond Crawford which is published at page 1195 of this issue. Dr. Crawford pleads for such assistance as will enable the sanatorium accommodation of the College to be brought up to date and made fully adequate. At present this is patently not the case. The wooden hut which is the only building available at the College at present for the isolation of all varieties of infectious disease is far from fulfilling the most elementary requirements for a school of its size. In the light of modern knowledge the sanatorium must also be considered unsuitable; it is not only inadequate, but also uneconomical to administer. The situation of the general school buildings is fine and the régime healthy, and so far no serious emergency has arisen; but the steady growth of the College, due to its increasing popularity, has created a problem which the council is compelled to face without further delay. As Dr. Crawford observes, the College, with its Royal Medical Foundation, ought to be a model for other schools in respect of its medical equipment, instead of being compelled to look enviously at many other institutions where better conditions obtain. The provision of a modern, but not luxurious, sanatorium, and of an adequate isolation block, is an urgent necessity, and the estimated outlay of £25,000 cannot be regarded as extravagant. Experience shows that for a school of this size the main sanatorium should afford accommodation for twenty boys, and the isolation block be ready to receive forty in the event of an epidemic. It is a reproach that the sons of medical practitioners during their education should be at a disadvantage

in respect of their safety from infection and their treatment during illness as compared with boys who are being educated in schools less intimately associated with the medical profession. We can therefore support the appeal of Dr. Crawford with confidence that its justice will be widely recognized, as a matter of sympathy with individuals and of corporate pride in a great medical scholastic institution.

We have previously suggested that many would gladly contribute if they understood that even small donations were welcome. If every registered practitioner contributed 10s. this would supply the whole amount required; it is probable that very many would be glad to help if the claim of the College on their generosity were clearly presented to them. In the event of Branches and Divisions seeing their way to support the appeal shortly to be made by the British Medical Association Charities Fund, Epsom College, in common with other charities, will derive considerable benefit. Co-operation between the Association and Epsom College is becoming increasingly close, as is only right, and it may be mentioned that such difficult problems as the continuance of the education of a boy at the College when the death of his father—a medical practitioner—renders this impossible for financial reasons, are being sympathetically and practically considered. In our advertisement columns will be found information concerning the College, its foundation scholars and pensioners. Armed with such details medical practitioners may be able to bring the claims of the institution to the knowledge of those of the general public whose circumstances will permit them to make a return to the profession as a whole for services received from its members. Gratitude expressed in this way would be of lasting benefit to a school which has already achieved much and promises still greater results in the future.

## BACKFIRE FRACTURES OF THE FOREARM.

EVER since internal combustion engines, which the driver had to start with his own hand, came into general use fractures of the forearm have been well known to occur from the engine backfiring while the chauffeur is in the act of turning the starting handle. The exact mechanism of these fractures and their varieties have been little investigated, and their treatment has been passed over by most authors, who have included them in general terms among fractures of the same region from other causes. It was time that more exact knowledge of their pathology and treatment was put on record, as Mr. Harold C. Edwards has done in the October number of the *Journal of Bone and Joint Surgery*,<sup>1</sup> the official publication of the American Orthopaedic Association and of the British Orthopaedic Association. Mr. Edwards deals with an experience of forty-two fractures which were treated in the fracture department of King's College Hospital.

All these fractures occurred in the lower third of the radius, but sometimes the styloid process of the ulna is broken off, or more rarely the shaft of the ulna may be fractured. From the histories given it is in some cases impossible to decide whether direct or indirect violence caused the fracture, for the shock of the explosion and the rapidity of the movement causing the injury may render the subject of it unable to follow the sequence

<sup>1</sup> *The Journal of Bone and Joint Surgery*, vol. viii, No. 4 (Old Series, vol. xxiv, No. 4), Boston, Mass., October, 1926, p. 702.

of events. In some instances the history given is clear, to the effect either that the handle was torn from the grasp and flew round and struck the forearm or wrist, or that, despite the explosion, it did not leave the chauffeur's hand. But in other cases all that the sufferer knows is that something happened and he found himself nursing a damaged limb. The precaution adopted by many chauffeurs of keeping the thumb behind the handle, parallel with the second metacarpal bone, instead of encircling the handle, does not seem to be very efficacious, probably because the consequent position of dorsiflexion is obnoxious.

Out of the forty-two cases recorded by Mr. Edwards, ten were situated at the junction of the middle and lower thirds of the shaft of the radius. (In one the ulna also was fractured.) These were all almost certainly due to direct violence. In eight the fracture was through the base of the styloid process of the radius, with or without fracture of the styloid process of the ulna. There were seven cases of "Colles" fracture, usually from indirect violence, six of "high Colles"—that is, from  $1\frac{1}{2}$  to  $2\frac{1}{2}$  inches above the lower articular surface of the radius—probably due to direct violence. In four the lesion was separation of the radial epiphysis, and in two fracture through the styloid process of the radius and posterior margin of the radial articular surface. The remaining five cases are classified as "mixed types," including injuries to the carpal and metacarpal bones. It thus seems probable that far more fractures are caused by indirect than by direct violence. It is of interest to note that in young persons (15 to 20 years), instead of separation of the epiphysis, as might have been expected, fracture occurs.

As to treatment, Mr. Edwards prefers Carr's splint after manual reduction, verified by  $x$  rays after the splint is applied. Early massage is to be avoided. When the fracture cannot be correctly reduced, or in old neglected cases, open operation and osteotomy is recommended. It is most important to correct the backward tilt of the lower fragment, which interferes with the proper play of the extensor tendons. In old cases the excision of a wedge of bone or the performance of a curvilinear ("ball and socket") osteotomy may be necessary to achieve this. For other interesting details of diagnosis and treatment we refer the reader to the original paper, which is worth study.

With the increased use of self-starters this injury may be expected to become rare among the drivers of light passenger and private cars, but the engines of the enormous and increasing number of heavy lorries, omnibuses, and charabancs are still started by hand, so that we must look forward to a continued supply of backfire fractures among their drivers for some time to come.

The publication of this paper, based on experience obtained in the fracture department of King's College Hospital, illustrates the advantages of this form of specialization. Had these forty-two cases been scattered among the services of various surgeons their systematic treatment and their collection and study would have been more difficult, and such results as could have been attained and recorded would almost certainly have been less valuable to the student and pathologist, and, last but not least, less satisfactory to the patients. We devoutly hope that the example of King's College and some other hospitals in the provinces as well as London will be generally followed as regards the treatment of fractures.

#### GIFT FOR MIDDLESEX HOSPITAL NURSES.

At a recent meeting of the court of governors of the Middlesex Hospital it was announced that Dr. W. Essex Wynter, consulting physician to the hospital, had formulated a proposal to devote, after his and Mrs. Wynter's deaths, his house, known as Bartholomew Manor, Newbury, and two groups of sixteenth century cottages, together with an endowment fund for their maintenance and upkeep, to the Middlesex Hospital, to be held in perpetuity as a home for retired members of the nursing staff. Bartholomew Manor is possibly the oldest intact dwelling-house in the country. As a social unit the manor certainly existed in Saxon days, consisting at the time of the Conquest of thirty primitive huts or hagea. Pembroke, the Earl Marshal, owned the manor in Stephen's time, and, siding with Matilda, he was involved in a dispute with the Church and was cursed, him and his seed; though each of his five sons succeeded to the manor of Newbury none left male issue. In the reign of Richard II the manor was valued at £3, while later the manor house and demesne lands were associated with Sandford Priory in the diocese of Salisbury. The ownership finally passed into the hands of the Crown, and Charles I granted the manor to the town of Newbury for a consideration, while the Church became possessed of the demesne. The Ecclesiastical Commissioners eventually parted with the freehold in 1888. Dr. Wynter is now in possession of the manor house, a demesne of four acres, and two groups of cottages. One group of four cottages fronts upon the pre-Roman road from Gosport to Birkenhead at the eastern boundary of the manor, and faces inwards over a little courtyard and low brick wall to where, across a long lily pond, lies the old garden of the manor. The other group lies south of the manor, and consists of twelve cottages built in 1550. These buildings were recently acquired from the corporation of Newbury on the undertaking that the group should be preserved in perpetuity. The manor house itself has been reverently and sympathetically restored, and the cottages are gradually being reconstructed with contemporary material, purchased here and there all over the country, so that the design and character of the beautiful old buildings is being preserved, while the interiors are being arranged to provide a comfortable sitting room, bedroom, kitchen, and modern bathroom. Two retired sisters are already living in two of these self-contained homes, and eventually there will be accommodation for some sixteen sisters and nurses, each independently housed, yet with a community interest and with spacious beautiful rooms in which to meet. This magnificent gift, unique alike in its beneficent purpose, its self-sufficiency, and its historical and artistic interest, has been received by the authorities of the hospital with the deepest gratitude. For many years Dr. Wynter has been devoting himself to the work of restoration and preparation, and by his thoughtful generosity he is providing a place of great comfort and happiness to which members of the nursing staff of the Middlesex Hospital will be privileged to retire. They will be fortunate.

#### THE WELLCOME RESEARCH INSTITUTIONS AND MUSEUMS.

THE reconstructed and enlarged museum and laboratories of the Wellcome Bureau of Scientific Research, which were reopened by the Minister of Health on December 8th, would surely have delighted the late Sir Jonathan Hutchinson, who put so high a value on the teaching power of a properly arranged and equipped museum, and showed his faith in them by maintaining three such at his own cost. Mr. Henry S. Wellcome, whose absence was regretted at the ceremony, may be said to have the Hutchinsonian vision, and fortunately is blessed with much greater means

of carrying out his ideas. Some men would have rested content with having founded and supported such institutions as the laboratory at Khartoum and the Historical Medical Museum in London, but these, great as they are in interest and in usefulness, form a comparatively small part of Mr. Wellcome's contributions to the progress of research and of scientific education. The ceremony was held in the hall of the new house erected by the Society of Friends in Endsleigh Gardens. Mr. Neville Chamberlain, who presided at the opening ceremony, attributed the extraordinarily rapid advances in scientific knowledge of late years to the free intercommunication of ideas and discoveries between workers all over the world. No doubt there is much in this explanation, but we are more inclined to lay stress on the development of education and the enormous increase in the numbers of those who give their lives to research and invention, fostered by endowments, and by the enlightened self-interest of leaders of industry such as Mr. Wellcome. Sir Walter Fletcher gave an address on research and citizenship, in the course of which he drew attention to the way in which capitalism had rendered scientific advances possible, whether the capital in question was in private hands or had been given by public-spirited individuals to public institutions or corporations. He mentioned Charles Darwin, among others, as an instance of the former kind, and Sir Isaac Newton of the latter. Trinity College, Cambridge, supplied Newton with the necessities of life as well as with instruments of research, and Darwin could never have devoted himself to his life-work had he not inherited private means. As Sir Walter Fletcher pointed out, while the Bureau of Scientific Research and the laboratories are devoted to discovery, the museum is intended to be a great educational force—"a sumptuously illustrated textbook" designed to supersede to a great extent the old oral method, which was well enough when books were few and museums non-existent. The museum is intended to interest and instruct the layman as well as the professional student, so that he may realize in some degree the meaning and the importance of scientific research; and the lessons somewhat tardily learned by the captains of industry during the last quarter of a century may be also driven home to the minds of the great body of intelligent citizens, who will thus learn to "understand something of the difficult and lonely path the pioneer investigator has to follow." Sir John Rose-Bradford, in proposing a vote of thanks, drew attention to the fact that the meeting was held in the building erected by the Society of Friends, and that one of that body—Mr. Joseph Jackson Lister, father of Lord Lister—rendered minute investigations more practicable by his improvements of the achromatic microscope. Inspection of the museum and laboratories followed on the formalities of reopening, and all must have been struck by the excellence of the arrangement of the wealth of material displayed and the systematic way in which the intended lessons were set before the beholder. Mr. Neville Chamberlain showed his interest by spending a good deal of time in the museum, guided by the director-in-chief, Dr. C. M. Wenyon. The museum consists of twenty small halls and numerous laboratories and workrooms, as well as a library; but we are told in the handsome illustrated book presented to visitors that, large as the exhibit is, it can only be regarded as a beginning. We wish continued success and expansion to all the institutions under the control of the Wellcome Foundation Limited.

#### AN ULTRA-VIRUS OF TUBERCLE.

Struck by the high mortality among infants born of tuberculous mothers, Drs. Calmette, Valtis, and Lacomme have carried out at the Baudelocque Clinic in Paris investigations into the causes of their death. Observations on 357

infants born from 356 tuberculous mothers, together with reports by the three investigators on a certain number of those infants who died or were born prematurely, were communicated last month to the Académie de Médecine by Dr. A. Couvelaire. Dr. Calmette and his colleagues have come to the conclusion that, apart from trans-placental transmission of tubercle bacilli *in utero*, which must be very rare, it is legitimate to assume that there can be transmitted through the placenta a virus of tubercle, which does not produce any specific anatomical lesion, but is indicated by the presence of an acid-fast bacillus in the lymphatic glands and viscera of the infant. The fluid from the glands or viscera, even after filtration through porcelain, will cause the same acid-fast bacillus to appear in the glands when injected into guinea-pigs. The result is the same whether the fluid is obtained from prematurely born foetuses, from infants who die in the first few weeks, or from those who die of common complaints and without progressive malnutrition. The infants from whom the fluid was obtained had been entirely separated from their mothers, and had not received doses of the vaccine B.C.G. Drs. Calmette, Valtis, and Lacomme have thus been brought to assert the existence of an ultra-virus of tubercle, capable of transmission through the placenta as through a filter; a virus of which Koch's bacillus is a resistant form. Dr. Couvelaire's report brings out also the interesting fact that since 1923 the mortality among the infants of tuberculous mothers in the clinic has been reduced from 33 to 7.2 per cent. The higher mortality was due to imperfect separation of the infants from their mothers. The improvement has been brought about by employing wet-nurses, by the careful introduction of artificial feeding, and by the employment of trained and attentive nurses.

#### MIRROR-WRITING.

THE classic instance of mirror-writing is the notebooks of Leonardo da Vinci. Leonardo is supposed to have deliberately adopted this style of script as a sort of code to protect his writings from ecclesiastical censorship. But in certain of his drawings also the obliquity of the shading suggests that the pencil was held in the left hand, and Cardinal Louis of Aragon, who visited him during the last two years of his life, stated that he was suffering from some form of paralysis which impaired his manual power. It seems possible, therefore, that the mirror-writing of the man whom Browning assigned to cover one of the walls of the New Jerusalem was a consequence of right hemiplegia. Dr. Macdonald Critchley, who read a paper to the Neurological Section of the Royal Society of Medicine on December 9th, showed a number of examples of mirror-writing by right hemiplegics, but he added that the same phenomenon was found in some normal children just learning to write, as well as in more backward and feeble-minded children, in whom it was particularly associated with left-handedness. He recalled that mirror-writing was not uncommon among the insane also, and it was seen, again, in cases where there was partial switching off of consciousness or attention, as in certain states of hysteria, during the effect of depressive poisons, and in mediums at spiritualistic séances. Mental abstraction might in some cases lead to mirror-writing, and telegraphists had been observed to jot down messages mirror-fashion with their left hand while their right hand was on the keys. Dr. Critchley expressed the view that an adequate explanation of the condition would include both physiological and psychological causes, which entered in different proportions into different cases. From a physiological point of view it had to be remembered that centrifugal movements were the most common for both hands, and that most of the natural movements of one hand were the mirrored replica of those

of the other. The right hand, for instance, drawing a line with chalk on the blackboard, would draw naturally from left to right, and the left hand from right to left; the circle would be drawn clockwise with the right hand, anti-clockwise with the left. The repetition of such a highly complex act as writing facilitated subsequent performance of the same act, which became more automatic and less a matter of attention. But the question was, why did not everyone write mirror-fashion when using the left hand? The main reason, he suggested, was education. People had learned, as the result of experience, that writing, in European languages, ran from left to right; consequently mirror-writing struck them as being incorrect. But in certain cases in which this faculty of perception was in abeyance mirror-writing was apt to appear, and severe damage to the left brain also favoured this manifestation. Even in the normal and educated child the habit of forming such letters as "s" and "m" the wrong way round might persist for some time. Except in hemiplegia and congenital word-blindness, the mirror-writing patient usually realized that something was wrong with his script, and as a rule he could not read it. Dr. Critchley had also some interesting reflections to make on the influence of the ancient alphabets. The Phœnician, from which the modern alphabet was derived, ran from right to left, and for a long period there was considerable doubt as to the orientation of words. In some ancient inscriptions the lines were found reading alternately from right to left and from left to right. A change in direction probably corresponded to an alteration of the handedness of the race. In the ensuing discussion Dr. George Jones said that although he had had the opportunity of observing many who wrote Hebrew, which was written from right to left, he had never come across one who wrote in the reverse direction, and it was interesting to speculate what sort of script would be produced by a writer in Hebrew or Arabic, the only two living Semitic languages, who took to mirror-writing. Dr. Critchley, however, said that he had had one patient who, though she spoke English, could write only Hebrew; and she had right hemiplegia, and thereupon wrote Hebrew mirror-wise—she still wrote the words as a whole from right to left (the proper direction), but she formed the letters the wrong way round, so that, to give an illustration in English, the "b" would be a "d." Dr. Percy Smith said that in his experience of mental cases he had not come upon one case of mirror-writing, but he himself, having been originally left-handed, and acquiring right-handedness, was able to do mirror-writing, and he recalled that a fellow student of his at St. Thomas's many years ago used to keep his notes in mirror-writing, apparently to prevent cribbing. Dr. Millais Culpin, in some interesting remarks on left-handedness, expressed the view that at some period the Semitic peoples must have been left-handed, and he quoted two passages in the Book of Judges (iii, 15-21, and xx, 16) in which emphasis was laid upon the skill of the left-handed. In Dr. Culpin's view left-handedness persisting in a right-handed race might be originally an expression of antagonism to environment or an unconscious protest against arbitrary conventions. Stammering, too, which resulted when the left-handed was constrained to use his right hand for the purposes for which he had hitherto used his left, was in the nature of a protest. A left-handed father frequently had a stammering child, possibly because, being a person of gentle obstinacy, he had pushed the child firmly and steadily along a particular road, and the stammer was a symptom of rebellion. As an instance of the curious manifestations of these reversals, Dr. Culpin mentioned the case of a girl who, when writing to her mother, always used her left hand and wrote mirror-fashion, but to her father and others wrote in the normal way.

## SIR JAMES CRICHTON-BROWNE.

IN his long life (for, in spite of perennial youth, he has many years of experience, grave and gay) Sir James Crichton-Browne has played many parts: as a scientific alienist he trained many in his special subject, and made the West Riding Asylum famous for the men who worked there for a time, such as Sir Clifford Allbutt, Sir William Turner, and Sir David Ferrier; as Lord Chancellor's Visitor in Lunacy for many years; at the Royal Institution; and as prince of speakers, especially after dinner. In *Victorian Jottings from an Old Commonplace Book* he has followed the example of his brother, the late Balfour Browne, in revealing some personal reminiscences, but they are veiled in the form of extracts from notes kept since student days, and, indeed, going back in substance to even earlier times. The reader, as he turns the pages full of kindly wit and shrewd wisdom, and now and then varied by deep feelings, as in the few lines on "The Death Chamber," can hardly help recalling Sir James's spoken words, with over happy phrase and appropriate story to adorn his point. Though a number of the "jottings" concern the humours of his professional experience, they do not, so to speak, smell of the shop. How seldom it is that a book like this, brimming over with stories, does not serve up at least a few venerable chestnuts; but Sir James has apparently given us only of his private store, and of personal experience. Many are the interesting personalities who appear, and of his own profession no one except Lord Lister has left such a deep and gracious impression as Dr. John Conolly of Hanwell, described as "a Wilberforce who devoted his life to the abolition of slavery of a particularly grievous kind." The coloured frontispiece is a most pleasing and life-like portrait of the author by "Spy." It is safe to predict that these jottings, which are Victorian only in date, will rapidly be sold out, for everyone who reads them will be struck with the idea that the book would make an appropriate Christmas present for his friends.

A UNIT FOR THE RESIDUA OF ENCEPHALITIS  
LETHARGICA.

LAST year the Metropolitan Asylums Board decided to establish at its Northern Hospital, Winchmore Hill, an experimental unit of 100 beds for children between 3 and 16 years of age suffering from the after-effects of encephalitis lethargica. Patients were admitted on November 13th, 1925, but the accommodation was not fully used until last April. The Board has now received from Dr. G. A. Borthwick, medical superintendent of the hospital, a report on the first year's working of the unit. Observation and research were at first hampered by the difficulty in securing resident medical officers, and no very definite curative results have been obtained so far; but the experiment has been full of interest, and the unit should at least prove valuable as a clearing house for patients suffering from the residua of encephalitis lethargica. On the advice of Dr. S. A. Kinnier Wilson, consulting neurologist to the Board's mental hospitals, no patient below the age of 3 years was accepted; hopelessly bedridden and slight cases with very few physical or mental symptoms were refused; patients reduced to the level of mental defectives were sent elsewhere; and no case of doubtful diagnosis was taken. The number of cases admitted during the year was 133. Of these, 12 have been discharged much improved, 6 were found to be in such a condition that further improvement was unlikely, 4 cases were unsuitable for the unit, and 18 patients were removed by their parents. The remainder are still under treatment. No death occurred during

*Victorian Jottings from an Old Commonplace Book.* By Sir James Crichton-Browne, M.D., LL.D., F.R.S. London: Etcchells and Macdonald. 1926. (Demy 8vo, pp. vii + 344; 1 plate. 15s. net.)

the year. The report gives a summary of the protean sequelae—moral, emotional, intellectual, and neurological—of the disease. The routine procedure in the unit is to give at first no treatment except ordinary school and hospital discipline. Later a complete physical and mental examination is made, and the patient is classified, and thereafter a record of progress is kept. Pituitrin and thyroid extracts have been given when endocrine balance is upset, and hyoscine, belladonna, nicotine, and parathyroid in Parkinsonian cases; sunlight treatment, massage, gymnastics, and electricity have also been used, and luminal and bromides in restless cases. Most of the children showed psychic changes; milder cases did well with the ordinary discipline of the unit, away from home surroundings and the liability to be spoilt or brutalized. Severe cases, with querulousness, outbursts of temper, lying, thieving, sexual erotism, etc., improved only slightly, and showed a tendency to relapse. Dr. Borthwick advised that the unit should be continued for at least another year for further observation and research, and his recommendation has been approved by the Metropolitan Asylums Board. The report concludes with observations by Dr. T. H. Whittington, the visiting oculist, on ocular signs in 99 of the children. His general impression is that the ocular signs so common in the acute stage of the disease are comparatively rare in the post-encephalitis stage. Nineteen children, however, showed weakness of convergence; in twelve cases there was marked external strabismus; while the screen test showed the same symptom in six other cases.

#### THE CARE OF THE MENTALLY DEFECTIVE.

SEVERAL circumstances have lately combined to draw attention to the question of the provision that should be made for the mentally defective. At the recent conference held under the auspices of the Central Association for Mental Welfare one session was devoted to a consideration of the care of the mentally deficient outside institutions, and another to the need for the careful selection of children for special schools and the training of teachers for service therein. The Mental Deficiency Bill, which has been before Parliament this session, has been withdrawn, owing to the opposition which has developed at a late stage, due, it would appear, chiefly to objections to the definition of mental deficiency it contained, which is considered to be too wide. With the bill the hope of an administrative reform which has long been desired disappears; the bill proposed to give additional powers both to education and mental deficiency authorities in the classification of children leaving the special schools. It would have allowed education authorities to notify to the mental deficiency authorities children leaving the special schools, not merely for institutional care and for guardianship as hitherto, but for supervision also. Several important institutions for the feeble-minded have just issued their annual reports, and it is interesting to note and compare two of these which have been sent to us from the same area—that of the Royal Albert Institution, Lancaster, for the feeble-minded of the northern counties, and that of the Lancashire and Cheshire Society for the Permanent Care of the Feeble-minded, with special reference to the Sandlebridge Institution. It is increasingly recognized, as was emphasized at the conference above referred to, that while feeble-mindedness must always of necessity remain a lifelong condition, quite a large proportion of those so afflicted are by no means anti-social in their behaviour, and can even be described as not entirely unsuccessful members of the community in the more humble spheres of life. With suitable instruction in the special school up to the leaving age of 16 years they are able, with a small amount of sympathetic supervision and control, to fill a useful place in society. A large number of mentally

defective persons, though probably a minority of those above the class of imbeciles, need permanent care in institutions or colonies. They need this for their own safety and happiness, for the relief of those who would otherwise be overburdened and crippled by the care they would have to give them in their homes, and in order to protect the community from their anti-social behaviour and relieve it from their complete economic uselessness. The former of the two institutions named above has the permanent care of some 800 inmates, and the latter of about 320. They are supported by payments from public authorities on account of feeble-minded persons for whom such authorities are responsible, and by voluntary contributions. A large number of devoted workers, paid and voluntary, medical and lay, are associated with their work and contribute to its success. The accommodation provided by such institutions throughout the country is as yet quite inadequate to the needs of the situation, and further pressure from public opinion and further increase of private benefaction are both required in order to stimulate further provision. The general nature of the work done in such institutions can be gathered from their annual reports. The variety of occupations or trades in which the inmates are instructed and engaged is very wide, and it is interesting to note how largely many of these, especially gardening and farming, are carried towards economic success, in addition to their great value for mental activity and social usefulness.

#### VISUAL STANDARDS FOR MOTOR DRIVERS.

THE increase in the number of accidents due to motor vehicles is naturally arousing a good deal of public attention, and there have been demands for the routine physical examination of drivers, especially of heavy commercial vehicles, before a licence is granted. It may be interesting, therefore, to recall the recommendations made about a year ago by the Ophthalmological Section of the American Medical Association with regard to vision of drivers of motor vehicles; they are two in number. The first was that the applicant must have vision of at least 20/50 in one eye and of at least 20/100 in the other eye, with or without glasses; applicants with less vision than 20/100 in the poorer eye may, under certain conditions, be qualified by a special board or county board. The second was that double vision shall disqualify. Each State was advised to establish a board consisting of two general practitioners or surgeons and one ophthalmologist, and that to it should be referred doubtful cases. It was suggested that persons with vision less than 20/100 in the worse eye, or even when this eye is blind, may in some cases be passed provided the vision of the remaining eye is superior to the general standard, and reaches 20/30 without the aid of glasses. It was ascertained that fifteen States required all drivers to be licensed; twenty require licences for those who drive for pay; owner-drivers do not need licences. Thirteen States require no licences at all. Thirteen States provide that all applicants for drivers' licences must pass a specified examination. The tests are varied; some relate to vehicle regulations, others to the mechanism of motor vehicles, personal road demonstrations, and one subjects wage-earning drivers to both an oral and a written examination. Twenty-two require no examination. Pennsylvania is the only State in which the law is mandatory for all drivers, providing that no licence shall be issued to any person who is physically incapacitated. A physically incapacitated person is defined as "any person who has lost the use of one hand or both, or who has lost the use of both feet, or whose eyesight is so impaired that with the aid of glasses he cannot distinguish substantial objects clearly at a distance of 150 feet, or who shall have less than 20 per centum of normal vision . . . or shall have less than 2 per centum of normal hearing."

## THE MEDICO-LEGAL SOCIETY.

LORD JUSTICE ATKIN AND MR. JUSTICE GREER ON  
"IRRESPONSIBILITY."

THE annual dinner of the Medico-Legal Society took place on December 10th, with Lord Justice ATKIN, the president of the society, in the chair. Among the guests were Mr. Justice Greer, Sir John Rose Bradford, P.R.C.P., Dr. A. H. Coley (president, Law Society), Sir T. R. Hughes, K.C. (president, Council of the Bar), and Lieut.-Colonel C. T. Samman (warden; Apothecaries' Society).

The toast "Medicine and the Law" was in the hands of Dr. A. S. WOODWARD, who gave some amusing instances of how medical men in the witness-box had "floored" the cross-examiner. He himself appeared as witness in one case which turned upon the question whether a head injury could have been inflicted with a hammer. In reply to repeated questions from the barrister, he maintained that the injury could equally have been inflicted by a hammer or by a fall, and added that there was no standard for the force with which a hammer might be used. "That is what I understood you to be saying for the last five minutes," said the magistrate; "there is no standard for the force of a hammer, or for the thickness of a skull!"

SIR JOHN ROSE BRADFORD elaborated the customary parallels between the legal and the medical professions. Both had the same objects, the elucidation of truth and the welfare of the community, but they went about it in different ways, and he confessed that the way in which the law arrived at its conclusions, by opposing arguments before a jury of twelve persons, struck him as curious. Perhaps the main difference between the problems which the law had to solve and those which confronted the medical profession was that the former were set by men and the latter by Nature. The latter, accordingly, were the more complex and difficult, and there was no appeal. Dr. COLEY, who also responded to the toast, quoted a dictum which he attributed to Gladstone—that the two professions must always flourish, because the one is founded on disease and the other on dissection.

Mr. Justice GREER, who proposed the health of the Medico-Legal Society, said that members of both professions had to make important inferences from imperfectly ascertained facts. The medical man had to judge a patient's health or malady without absolute information as to his interior condition, and to some extent from subjective symptoms; while those who sat on the bench had to decide an issue on the evidence of witnesses whose observations might be imperfect, and whose honesty, in some cases, left much to be desired. But on the whole both professions arrived at sound conclusions. Their work was not entirely on parallel lines, for they were often brought into contact, and occasionally into conflict. In two branches of work medical men and lawyers were alike interested. One of these was the effect of nervous shock. It was extremely difficult to judge the precise nature of such an effect, and for his own part he was always inclined to give the benefit of the doubt to the sufferer. The other subject was mental disease. Here many doctors took a different view from the lawyers, though he did not think there was so much difference between the two as at first sight appeared, because the problems which the two professions had to investigate were not the same. The problem at a trial was not whether an accused person was suffering from mental disease, but whether the mental disease was of such a character that he was not responsible for his actions, or, to apply the M'Naghten test, whether his mind was in such a condition that it was not influenced by the fear of punishment. People who could be influenced by the fear of punishment should, in the interests of society, be punished for wrong-doing. But it did not follow that a man who was held to be not insane within the meaning of the criminal law was a man not subject to mental disease. The law was compelled to act with great stringency, though the effect of it might at times be modified by those who advised His Majesty in the exercise of his prerogative of mercy. Personally he thought that juries were inclined to take the medical view, influenced no doubt by what was known as the "unwritten law," and to find insanity where,

strictly, according to the criminal law, it ought not to be found.

Lord Justice ATKIN, in responding, said that the Medico-Legal Society was in a very healthy condition, with a membership of over 300. The interesting proposal had been made that the society should be represented at the meeting of the British Medical Association in Edinburgh next July, when the Section of Forensic Medicine would meet under the presidency of one of the society's distinguished members, Professor Harvey Littlejohn. He himself had been asked to serve as Vice-President of the Section, but unfortunately the meeting was held at a time of year when his judicial duties made it impossible for him to attend. Taking up a remark of Dr. Woodward's to the effect that while the law dealt in dogmatism and certainty, the doctor was concerned with theories and possibilities, the Lord Justice said that he was not sure that, unaided, he would have arrived at that conclusion. He was bound to defend legal procedure, and he thought that there was no better way of arriving at truth than a close examination and cross-examination of witnesses, and if medical men practised a similar method in dealing with their cases they might be more sure of their diagnoses. Sir John Rose Bradford had said that it must be difficult for a jury to arrive at a verdict. Certainly it was, especially because, on occasion, the twelve honest men had to decide, not only when lay testimony conflicted, but when eminent doctors gave contrary evidence, so that from medical evidence it might not even be possible to say whether a collar-bone had been broken! Nevertheless, he thought that both doctors and lawyers achieved a considerable degree of success.

On the question of insanity and criminal responsibility (Lord Justice ATKIN continued) there was a time when the two professions were in constant opposition, but to-day the conflict between insanity as understood by lawyers on the one hand and by doctors on the other had lost its sharpness. The reconciliation of the views of the two professions was very important, and he begged all concerned to abstain from epithets and from language which indicated a want of appreciation of the other point of view, and tended to emphasize the differences between the two professions. He went on to allude to the recommendations of the Committee on Insanity and Crime, appointed by the Lord Chancellor in 1922, over which he (the Lord Justice) presided. The view of the committee was that if a person, owing to insanity, was totally incapable of restraining his actions because of an irresistible impulse produced by the disease, he ought to be held criminally irresponsible. A high judicial authority had pronounced that idea fantastic, but so far from being fantastic the Lord Justice thought it unanswerable. ("Hear, hear.") The doctrine was recommended to the committee by the British Medical Association and by the Medico-Psychological Association, who, although they wanted much more than that, at all events accepted that point of view. It was accepted also by the lawyers composing the committee, including such eminent authorities as Sir Archibald Bodkin, Sir Richard Muir, Sir Herbert Stephen, and Sir Ernlley Blackwell of the Home Office. There had never been since English law was administered four men of more complete experience and knowledge of the phenomena connected with crime and the responsibility for crime. Another member of the committee was Sir Edward Troup, formerly Under-Secretary of State for the Home Office, and those who knew Sir Edward regarded as extremely amusing the idea that he would commit himself to anything "fantastic." The Lord Justice instanced a typical case, that of a mother with an impulse to kill her child, who fought against it, prayed to be delivered from it, but gradually found the impulse gaining ground until at last she yielded. The woman knew what she was doing, and knew it was wrong, because she had prayed to be delivered from it; and it appeared to him to be a ridiculous suggestion that in such a case the woman was not criminally irresponsible by reason of the impulse which arose from a diseased mind. The real fact was that every humane person on the bench would see to it that in such a case she would be held criminally irresponsible, even under the present law. It

was quite impossible for judges or other people to dig themselves into the trenches and to resist the gradual development of the law in respect to matters such as these:

In conclusion, the Lord Justice added that there was another medical question which had become of very great importance in the sphere of law of recent years. It had been his lot during the last few weeks to deal with cases under the Workmen's Compensation Act, and he had been very much struck with the large proportion of cases which arose now in connexion with industrial diseases. The schedule of industrial diseases had been extended from time to time, and would be further extended as medical knowledge increased and as administrators became more receptive to the advance of such knowledge. There was no doubt that this was a most humane provision. He thought it would be to the great advantage of members of the legal profession who practised in such matters that they should become more or less familiar with the kind of problems that arose in respect to industrial disease, and very important for medical practitioners also who practised in industrial districts that they should familiarize themselves with the questions of law that arose in the working of the Act. There were a good many pitfalls in the Act still, and he could imagine nothing more useful than a mutual arrangement of lectures on the subject, lawyers lecturing to doctors on the one hand, and doctors to lawyers on the other.

## England and Wales.

### COMPLIMENTARY DINNER TO SIR BERKELEY MOYNIHAN.

SIR BERKELEY MOYNIHAN, Bt., P.R.C.S., was entertained at dinner at Leeds, on December 8th, by his colleagues of the British Medical Association in Yorkshire. Mr. Alfred Gough, chairman of the Leeds Division, presided, and proposed the toast of the evening, "The President of the Royal College of Surgeons." He said that the election of Sir Berkeley Moynihan did not amount to the conferment of a distinction, but rather the recognition of distinction. Sir Berkeley Moynihan had been for a quarter of a century one of the most prominent figures in British surgery, and his supremacy was unchallenged in the sphere of the upper abdomen. His wide knowledge of literature, art, music, and the drama was well known, and his marvellous physical energy and capacity for work resulted in a uniform efficiency of 100 per cent. Mr. A. L. Whitehead, consulting ophthalmic surgeon to Leeds General Infirmary, referred to the association of Sir Berkeley Moynihan with Jessop, McGill, Ward, Littlewood, and Mayo Robson at Leeds Infirmary, and added that he had acquired the best from all of them. The publication of his book *Abdominal Surgery* had aroused the profoundest interest throughout the world, and particularly in America. After referring to Sir Berkeley's insistent attention to detail and his wide general outlook, Mr. Whitehead said that his great powers of organization and administration had brought him fresh honours during the war, while as a writer he had produced many works of great distinction, literary value, and clarity of expression. His latest effort—the appeal for the Cancer Research Fund, which had brought in £130,000—owed its success to his great influence and power of putting a case. Dr. A. Hawkyard paid special tribute to Sir Berkeley's gift of oratory and his mastery of the written word.

Sir Berkeley Moynihan, in response to the toast, mentioned that he had been originally intended for the army, but he had chosen the path of saving life rather than destroying it. In his student days, and later, he had owed everything to Jessop and McGill. The pre-eminence of Leeds in surgery was due to its having produced such men with great creative minds as Spencer Wells, William Hey, and Mayo Robson, together with many great exponents of the new ideas in surgery. When he first joined the staff at Leeds Infirmary there was little reciprocity between surgeons, and so he had established the first surgical club in England; that club had now three

descendants, only one of which had flagged. After a great many difficulties the *British Journal of Surgery* had been founded to give to surgery a chance of expression through the medium of a periodical devoted exclusively to its science. The real heritage which a man could give his profession was the training of men inspired by his ideals. He thought that the chapter of the Listerian epoch was now closed, and that surgery would now advance by harking back to biology in its broadest sense, and by proceeding hand in hand with physicists, biochemists, chemists, and pure physiologists. Such was the conception behind the present Cancer Campaign, and he was proud to know that Leeds had at its disposal for research more money than any other place in Europe. The tribute he had received that night touched him very deeply as relating to something he valued even more—namely, the tradition Leeds had set up a century and a half previously, and had never allowed to weaken since. He valued most the acknowledgement by the people among whom he had lived and worked that he had been loyal to this great tradition.

### PROPOSED SPORTS GROUND FOR LONDON UNIVERSITY.

An appeal for funds for an athletic ground and boat-house is being issued by the University of London, and eleven medical members of the Senate have addressed a letter in support of it to all medical graduates of the University and medical practitioners who were educated in the metropolitan medical schools. Some twenty-eight acres of land have been secured at Motpur Park, near Wimbledon, for about £18,000, and for the boat-house two acres of land at Chiswick at a cost of £4,000. The total cost, including the preparation of the ground, the building of the boat-house, and an endowment for running expenses, is over £70,000, half of which it is estimated will be met by contributions from the colleges, schools, and students. The Chancellor, Lord Rosebery, has given £5,000, and the Senate has also granted £5,000. In view of the prominent position in the University of the faculty of medicine and the existence in London of so many leading medical schools, it is hoped that members of the medical profession will subscribe generously towards these urgently needed facilities for students. Cheques should be made payable to the "University of London Athletic Appeal Fund," and be sent to the Financial Officer, University of London, South Kensington, S.W.7.

### MEDICAL AND DENTAL TREATMENT OF LONDON SCHOOL CHILDREN.

It was reported to the London County Council on December 14th that the attendances of school children at the treatment centres had been satisfactory during the past year. The demand had been greater than could be conveniently dealt with at the centres, in part owing to the reluctance of the general hospitals, except under the Council's scheme, to treat school children to the same extent as formerly. Some 4,000 additional children requiring eye treatment were noted at the routine inspections during 1925 as compared with 1924. Five in-patient centres for throat operations have been approved; three of them are open, and the other two will be ready in January. Arrangements have also been made with the Princess Louise Hospital, North Kensington, and the Victoria Hospital for Children, Chelsea, for the treatment of 500 and 440 throat cases respectively a year as in-patients. The gradual decline in the number of cases of ringworm, owing to the successful results of x-ray treatment, continues; provision is to be made for only 1,300 such cases next year. The six centres at present in operation for remedial courses for stammering children are to be continued. The total cost of the arrangements during the next financial year will be £97,878, of which treatment for diseases of the eye, ear, nose, and throat, and for ringworm accounts for £23,066, of minor ailments for £27,066, and of dental cases for £43,916. The total represents an increase of just over £3,000 on the expenditure authorized for the current year.

### PRACTITIONERS' FEES IN MIDWIFERY CASES.

The Midwives and Maternity Homes Act, 1926, provides that any medical practitioner called in to the assistance of a midwife shall submit his claim for payment within two

months of the date on which he was summoned. The London County Council, immediately the Act came into operation, took steps to notify those practitioners who were known to the Council to undertake these cases, but with regard to others it placed reliance upon notices which appeared in the editorial matter of the professional journals. In several instances practitioners have submitted claims after the expiration of the two months prescribed, but the Council took the view that they were not aware of the provisions of the Act, and that it would not be politic to insist upon strict compliance with the law. It was understood that the Minister of Health would be prepared to consider favourably an application by the Council for permission to pay such claims if submitted before the end of 1926.

## Scotland.

### GLASGOW MATERNITY AND CHILD WELFARE SCHEME.

BRIEF reference was made in the JOURNAL of December 11th (p. 1140) to a pamphlet describing a scheme for maternity and child welfare in Glasgow prepared by Dr. A. S. M. Macgregor, M.O.H., at the instance of the health committee of the corporation. The scheme is under the general direction of the medical officer of health, and the child welfare staff includes eight medical women and thirty-nine nurses. The home supervision of children is carried out by co-operation with a voluntary Infant Health Visitors' Association. There are fourteen local clinics or consultation centres, of which three are new and specially designed. The West Govan clinic, just completed, was erected at the cost of the city. It will be conducted and partly maintained by a voluntary association, under the convener'ship of Lady Helen Graham, which has for long done pioneer work in the area. In 1925 there were three ante-natal clinics, and three more have since been added. The Glasgow Royal Maternity Hospital forms an important link in this part of the scheme. An infant consultation and an ante-natal clinic are held there and twenty-five beds are reserved for ante-natal cases. Artificial light treatment is provided in the new annexe to the municipal buildings. The running cost for current and carbons has been less than 3d. for each exposure, which, at an average of twenty-four exposures, amounts to about 1s. 6d. a course. Venereal cases emerging in maternity and child welfare work are treated at district clinics, which constitute a part of the scheme. Milk and meals for expectant and nursing mothers and children up to 5 years of age are supplied to necessitous cases on conditions. There were 1,650,796 pints of milk issued during 1925, at a cost of £17,000. The day nurseries or crèches directly managed by the corporation are five. A kindergarten at Phoenix Park, which belongs to the city, and a similar institution in Anderston under the Queen Margaret College settlement, which is aided by a grant from the city, are staffed by voluntary workers. Three country homes are maintained under the scheme at Mount Vernon, Scotstoun, and Mount Blow for children suffering from rickets, malnutrition, or debility after acute illness. The Garscube Cottage Hospital, to which Sir Archibald Campbell makes an annual contribution of £300, is maintained by the corporation as a country home for mothers. Beds for ophthalmia cases, where required, are available in an adapted reception house. Domestic helps are supplied during the lying-in period, or if a mother is ill and her children are under 5 years of age; they are paid by the corporation at the rate of 5s. a day without food. The charge against the family is graded according to circumstances. Refresher courses are provided for midwives at the Royal Maternity Hospital. During the financial year 1925-26 the total expenditure on the scheme was £122,215. Deducting revenue, mainly Government grants, the balance was £71,895, equal to a rate of 1.663d. The city of Glasgow is to be congratulated on the scope and purpose of the foregoing activities. It is a notable feature of the scheme throughout that, where it comes into touch with voluntary organizations, it co-operates—it does not displace. Administratively this is common sense; it makes for elasticity

which, as Dr. Macgregor says in the booklet, is essential to a child welfare scheme, and it secures the practical sympathy of many whose goodwill is highly conducive to the progress and development of such work.

### INDUSTRY AND FATIGUE.

An address on industrialism and fatigue was delivered on December 10th by Dr. A. K. Chalmers, late M.O.H. for Glasgow, to the Glasgow Charity Organization Society. The avoidance of industrial fatigue was now, he said, based on accurate knowledge of many factors affecting health. Legislation during the nineteenth century had resulted from the public recognition of conditions injurious to health, but in the twentieth century it had gone further, and inquired into the conditions necessary for maximum efficiency of workers. The present view seemed to be that maximum efficiency was reached gradually with each day of the week, whereas, according to older views, it was supposed to be reached early in the week. It had been found that the best temperature for heavy work was 55° F., and for light work, such as that done in an office, 65° F. Efficient ventilation was also a necessity, as well as adequate food. The new spirit underlying the industrial welfare movement was important, and ought to be extended.

### ENTHUSIASM FOR HEALTH.

A lecture was delivered by Professor J. Arthur Thomson on December 7th, under the auspices of the Glasgow Corporation. Taking as his subject "Education towards health," the lecturer made a plea for fostering an enthusiasm for health, which should mean much more than the absence of disease, for it included positive vigour, resisting power, initiative, and joy in living. In schools, the enthusiasm for vigour and fitness might be achieved by hero-worship, by appraising health achievements, by broadening the concept of play, and by evoking admiration for the superb healthfulness of wild animals. The three great informative studies were history, the world without, and the laws of health and happiness. The last were badly in need of emphasis. Every young citizen should understand the general working of the human body, the common-sense ways of fostering health and avoiding disease and the fundamental facts in regard to heredity. For lack of these progress was hampered. When the growing person fell into sub-health a vicious circle was apt to be set up, because energy for exercise, open air, and resistance was sapped and the bodily tone deteriorated. On the other hand, when the thrill of health was increased by exercise, games, excursions, and the like, a virtuous circle was produced, for it was a feature of healthfulness to wish to be healthier still. More biology and natural history should be taught in schools, not only for their own sakes, but as the essential counter-activities in a mechanical age.

### VITAMINS IN RELATION TO INDUSTRY.

At a joint meeting of the Edinburgh and East of Scotland Sections of the Society of Chemical Industry and of the Institute of Chemistry on December 8th a paper on vitamins in their relation to industry was read by Mr. F. H. Carr, C.B.E. After tracing the history of vitamins during the past fourteen years, he discussed the action of the different vitamins. Deficiency of vitamin A caused a failure of growth in experimental animals, and of vitamin B a form of neuritis. The absence of vitamin C over a long period was productive of scurvy. Insufficiency of vitamin D in the food of children led to rickets; it appeared to be a substance distinct from vitamin A, with which it had long been confused. For the first three vitamins animals and man were dependent on the vegetable kingdom, but vitamin D appeared to be produced in the animal body by the influence of sunlight or other source of ultra-violet rays, so that when diet was deficient in this vitamin rickets was not developed so long as the growing body obtained a sufficient amount of radiation. Recent work had pointed to the presence of a fifth vitamin, known as vitamin E, which was present particularly in the germ of wheat. The practice of eating white bread, he considered, was thoroughly to be condemned, because it was lacking both in vitamin B and vitamin E. Mr. Carr described methods whereby the

vitamin-containing parts of food materials could be extracted in highly concentrated form, and he also demonstrated the test by which the vitamin activity of cod-liver oil could be ascertained as satisfactorily as by animal experiments.

## Correspondence.

### EPSOM COLLEGE.

SIR,—I ask every medical practitioner to be so patriotic to his profession as at least to read this letter. Epsom College needs a new sanatorium and isolation block. The existing one is out of date in its accommodation and arrangements, is uneconomical in its working, and affords no facility for the isolation of infectious cases. This purpose, of such paramount importance in a public school, is at present effected by a wooden hut, which is licensed only for a few years more. The vacated sanatorium would, however, with a limited amount of internal adaptation, provide excellent residential quarters for at least forty more boys, and so enable the council to house some of the numerous applicants whom it has to refuse annually.

Epsom College, as the offspring of the medical profession, should show a sanatorium that would be a model for all other schools to copy. Such an object should appeal to the pride as well as to the philanthropy of the profession, and some £25,000 is a sum that would enable us to gratify both. We cannot hope for many large donations from a profession in which few are rich, but no other profession has more ready access to rich laymen, who may desire to bestow some of their wealth on suitable objects of charity. Here is an object that combines an educational with a philanthropic purpose.

There are over 50,000 practitioners on the *Medical Register*. Ten shillings from each would provide this haven of rest for the reception of sick sons of generations of medical men, and perhaps for your own. But as experience has taught us that such a unanimous response is not to be looked for in our, or indeed in any, profession, we ask those who can to send larger donations to compensate for those who send nothing. Annual subscriptions do not even afford the balance required for maintenance, so that for all structural improvements we have to depend on legacies and extraordinary donations. Remember "Qui facit per alium facit per se," and great gratitude will be due to those who can supplement their own gifts by influencing donations from others.

The donor of £10,000 may give his own name, or the name of any person whom he or she desires to commemorate, to the main block of the sanatorium, and the donor of £5,000 may do likewise to the isolation block. A large ward may be named for £3,000, and a small ward or the casualty department for £1,000, while £100 may determine the name of a single bed. Each medical school might well confer its name on a single bed. Votes at the annual elections of foundationers and pensioners are given for subscriptions and donations to the new sanatorium fund.

This complete scheme should not be beyond the ready accomplishment of the profession with the help of some of those not rare persons who feel that they owe a debt of gratitude to some honoured medical attendant. We can do it, if we have the will to do it, but this condition is an essential prerequisite.

The *British Medical Journal* and the *Lancet*, of their goodness, have promised to publish lists of all subscribers, both small and great, from time to time. I beg you to figure on these lists by sending what you can to the "Sanatorium Fund" to the Secretary at the Epsom College Office, 49, Bedford Square, W.C.1, or to the office of either of the above-named journals to the credit of the fund.—I am, etc.,

RAYMOND CRAWFORD,  
Chairman of the Council of Epsom College.

### TREATMENT OF CANCER BY OÖPHORECTOMY.

SIR,—In his observations on the Liverpool demonstration of the lead treatment of cancer (December 11th, p. 1135) Dr. R. G. Canti makes the statement that "it is the first time in history that a generalized treatment has been found that brings about a local disappearance of a cancerous growth." I consider this is incorrect, for the same thing has taken place in mammary cancer under oöphorectomy—in every respect a generalized treatment, and it has done this, not only in my own hands, but in that of others. We have Lett's exhaustive study of 99 cases in support of this fact, and I have in my possession a letter from the late Dr. Herman of London telling me of a case under his care where for an extensive recurrence after removal of the mamma the late Sir Frederick Treves advised amputation at the shoulder-joint. The suggestion was not carried out but oöphorectomy done, with the result that within a year all local traces of the disease had disappeared, the patient living for eight years and dying eventually of a renal tumour. Again, the late Sir Alfred Pearce Gould in his *Bradshaw Lecture on cancer* (December 7th, 1910) gives two very typical cases of mammary cancer illustrative of the salutary effects of oöphorectomy, and in conclusion, speaking of one of the cases, he says: "I saw this patient last month (November, 1910), after an interval of ten years, and found her enjoying excellent health; the scars of her numerous operations are the only signs that she has ever been the subject of cancer." In veterinary work, Mr. Frederick T. G. Hobday of London wrote me in 1922 that he also finds oöphorectomy serviceable in vaginal cancerous growths of animals.

In view of evidence such as the above I feel I am justified in calling in question the correctness of Dr. Canti's statement that the lead treatment has been the first in history to bring about the local disappearance of a cancerous growth. This effect was observed as far back as 1896 under oöphorectomy. I admit the results in the oöphorectomy cases were often not permanent, and time may show the same feature in the lead-treated cases that now promise well. An explanation of non-permanency in the oöphorectomy cases may be the fact to which Mr. Hobday drew my attention, and that is, that I was wrong in stating that oöphorectomy permanently maintained the milk supply in cows. In three or four years its effect passed off. This being so, the same may take place in the human subject, and account for the reappearance of the cancer. This does not, however, alter the fact that while the effect of the operation remains the cancer is controlled and overcome. I still feel that if we could fathom the *modus operandi* of oöphorectomy in cases of cancer we might get a clue to the nature and etiology of the malady, and that to ignore these results or sweep them aside as valueless is not a wise policy, nor is it prudent to indulge in over-laudation of a remedy until time has set its stamp on its real worth.—I am, etc.,

Glasgow, Dec. 12th.

GEORGE THOS. BEATSON.

### LEPROSY: ITS TRANSMISSION AND TREATMENT.

SIR,—Dr. Graham Little reports in your issue of December 4th (p. 1034) an interesting case of leprosy "cured" by vaccine treatment—a method which has been used for several decades either as tuberculin, which gives reactions in leprosy, or as killed lepra bacilli, with occasional recoveries such as occur after almost any treatment. When he goes on to say that "it is the general experience" that the products of chaulmoogra oil have not fulfilled the hopes held out by me, I am at a loss to know whether he is in ignorance of the many hundreds of early leprosy cases which have been cleared up recently by injections of the soluble products of chaulmoogra oil in Hawaii, Fiji, the Philippines, Korea, India, and elsewhere; or whether he seriously contends that the few negative results reported by London dermatologists (mostly in fairly advanced cases, which no one, as far as I know, has ever claimed to be able to clear up with certainty) completely outweigh the positive results in hundreds of cases treated by leprologists with infinitely more experience than it is possible to obtain in this country, working in the endemic areas with many

early and more amenable cases. If, however, he meant "the general experience of London dermatologists" I am quite ready to accept his statement—for what it is worth!

As a joint meeting of the Dermatological, Therapeutical, and Tropical Diseases Sections of the Royal Society of Medicine has already been arranged, at the request of the dermatologists themselves, for 5.30 p.m. on February 2nd, I suggest that it may be well for the medical profession to suspend judgement until a full report is available of what should prove a very interesting occasion.—I am, etc.,

London, W.1, Dec. 8th.

LEONARD ROGERS.

SIR,—While Dr. Graham Little is to be criticized for having omitted the word "apparent" before "cure" in his communication on the case of acute nodular leprosy, those of us who have lepers under our care should be grateful to him for bringing to our notice a new method of treatment.

The letter of Drs. Low, MacLeod, Manson-Bahr, and Sequeira, on the other hand, contains no useful information at all, and it would be interesting to know if any of these gentlemen have given this vaccine treatment a trial before making these discouraging remarks. Personally, I have already used Dr. Hasson's vaccine on a very advanced case of leprosy, which, for many other reasons too, had been given a hopeless prognosis. I am glad to be able to say that, although I have not achieved a cure in four weeks, I have had results which have been very encouraging, not only to myself, but also to the patient and her friends.

The extravagant claims for chaulmoogra oil by men "with long and close experience in the disease" were made in face of much evidence that, in this country at least, the drug has proved useless. Regarding the possible disappointment experienced by lepers who have happened to read the *BRITISH MEDICAL JOURNAL*, I would suggest that no patient nowadays of average intelligence expects his doctor to cure him, but he does expect that he will do his best, and at least prefers enthusiasm to despair.—I am, etc.,

Brighton, Dec. 13th.

J. H. T. DAVIES.

SIR,—May I answer my friendly critics very briefly?

I used the word "cured" upon the analogy of general experience in tuberculosis, to which leprosy is in so many respects similar. If a case of pulmonary phthisis loses under treatment all physical signs of the disease, and also all evidence of the presence of bacilli, the patient is currently regarded as cured, and for practical purposes he usually is. The salient features of the case I reported are, I submit: (1) The conversion of an apparently moribund man into a person who would pass anywhere as being in normal health; (2)—and most significant—the complete elimination of bacilli in blisters produced upon the site of lesions, a feature which is of radical importance, as bacilli are so readily demonstrated in leprosy as compared with tuberculosis; (3) the complete disappearance of clinical symptoms such as cutaneous manifestations, thickening of nerves, and alteration of sensation. I naturally emphasized the dermatological aspects of the case, which bring it into my province of practice; and I may have been influenced by the remarkable change in this respect to take a too optimistic view of the possible future developments. To meet criticism, I am prepared to qualify the word "cured" with the addition "as far as clinical and bacteriological evidence goes."

With regard to the second point made by my critics, the duration of the disease: The history which I gave seemed very definitely to date the onset with acute neuritis some weeks prior to the appearance of the rash. The incubation period of leprosy is known to be very uncertain. Norman Walker has reported a case in which there was evidence for a latent period of some forty years, and I have recorded leprosy in a German lady who developed the disease in England nearly thirty years after she had left a country where it was endemic, and where she had lived as the wife of an English engineer for eleven years.

My description of the case now under consideration claimed no more than the fact that clinical symptoms seemed to date its perceptible onset at a time when the

patient was residing in England, but did not exclude a much longer latent period, the estimation of which is largely guesswork, in which I do not propose to follow my critics.

It happens that, as I write, I have before me a letter from a provincial dermatologist, received within the last few days, giving results of a case treated with the same vaccine as that mentioned in my paper subsequently to the exhibition of my patient last October. In this new case, after a comparatively very short period of injections, the disappearance of clinical lesions was as swift and complete as in the case reported by me. Doubtless the method will be extensively tested, but so far as my—of course, very small—experience goes, I do not recall any other means of treatment which has shown such astonishingly rapid amelioration, as evidenced by bacteriological as well as clinical tests. Perhaps I may emphasize the fact that the method which I praise is not my discovery, nor have I taken any credit for it, so that my enthusiasm is entirely disinterested.—I am, etc.,

London, W.1, Dec. 10th.

E. GRAHAM LITTLE.

### THE PUBLIC, THE DOCTOR, AND THE MASSEUSE.

SIR,—Dr. G. Murray Levick's letter (December 11th, p. 1142) is most opportune. The increasingly important part in medical practice which diathermy and actino-therapy are destined to play will be generally acknowledged. It is therefore of supreme importance that these valuable remedial agents are not carelessly allowed to pass into unqualified hands. The remedy, which rests almost entirely with the medical profession itself, is, however, very simple.

In such conditions as early rheumatoid arthritis, Parkinsonism following encephalitis lethargica, neuritis, hay fever, and dysmenorrhoea (to mention only a few conditions at random), when medicinal treatment alone has been disappointing doctors should avoid telling the sufferer that nothing more can be done; this advice generally results in the patient rushing to the nearest unqualified practitioner. In suitable cases it is the bounden duty of medical men to advise their patients to have appropriate physical treatment.

When some doctors do advise the administration of diathermy or ultra-violet radiotherapy they often short-sightedly send their patients to the unqualified for treatment. These naturally, through lack of competent knowledge, generally obtain inferior results, and if a disaster, such as those described by Dr. Levick, should occur, it is often the doctor who sent the patient to the masseuse who incurs the brunt of the blame.

Rash suggestions like those recently made by an eloquent lecturer, not, however, in practice himself, advocating the universal installation of ultra-violet lamps in the home, are greatly to be deprecated, as they directly encourage the indiscriminate exploitation of physiotherapy by the unqualified.—I am, etc.,

Newcastle-on-Tyne, Dec. 12th

W. KERR RUSSELL.

### THE INFECTIVITY OF ERYTHEMA NODOSUM.

SIR,—Dr. Robinson's account in the *JOURNAL* of December 4th (p. 1049) of three cases of erythema nodosum occurring in close succession in three members of the same family living in the same house raises the interesting question of infectivity. Though the records are scanty, observers in this country, in other parts of Europe, and in America have recorded multiple cases in the same family and also small localized outbreaks in institutions, schools, and districts. In the *JOURNAL* for 1921 (vol. ii, p. 741) J. O. Symes of Bristol suggests that erythema nodosum is an acute specific fever. The evidence for this view is not convincing, and there is no proof that the disease produces immunity. Second attacks and relapses are known to occur. E. S. Stubbs had a patient with five attacks and another with three.

It would appear that erythema nodosum develops in the course of septic and bacillary infections. In moderate cases

the temperature rises to 102° F. for some days; in severe cases pyrexia may be present for a period up to three months. In streptococcal infections of the tonsils and teeth joint pains sometimes occur, but usually without swelling or redness of the joints. There may be transient systolic murmurs or tachycardia, followed by prolonged convalescence. The condition corresponds with a mild septicaemia, and the nodes would be analogous to the rose spots in enteric and the secondary eruption in syphilis. On this assumption infective material may conceivably pass from one member of the family to another and reproduce the same symptoms, including erythematous nodes.

The bulk of cases of the disease seems to be sporadic. In addition to septicaemia another important cause is a tuberculous bacillaemia. Such a well known investigator as Calmette upholds this view. I reported two cases associated with tuberculous bacillaemia in the JOURNAL for 1924 (vol. i, p. 422), and in the *British Journal of Tuberculosis* for January, 1925, reported other cases and reviewed recent literature dealing with its association with tuberculosis.—I am, etc.,

Derby, Dec. 6th.

JOHN A. WATT.

#### MINER'S NYSTAGMUS.

SIR,—I have just returned, on a visit, from Malaya, and received my copy of the *BRITISH MEDICAL JOURNAL* for October 23rd, in which is a letter from Dr. Percival, wherein he states that his assertion that there was a notoriously high percentage of cases of nystagmus at the South Moor Colliery twenty-five years ago is correct. Dr. Percival states that his assertion is corroborated by two owners' representatives and one representative of the men, and quotes figures showing the number of men employed.

In justice to myself, I hope you will allow me to make a further statement in support of my contention that the percentage was not anything like so large as inferred from the particulars given to Dr. Percival. In the first place, as to the number of men employed. I have a very good reason to know that in March, 1899, I was receiving contract pay from over 840 miners employed at the South Moor Collieries, of whom at least 800 were householders. This number did not include sons of miners living at home and working in the mines. Besides, there were many other householders and lodgers, employed at South Moor, who were attended by other doctors in the district, so I fail to understand how this number could have shrunk to 300 by 1901; in fact, I know that the number of men employed increased during that period. If Dr. Percival should choose, he could probably obtain from the South Moor Colliery offices, Newcastle-on-Tyne, a detailed account of all cases of illness or accident due to employment during the period he mentions, as all such cases were attended by me and a list of them sent to the company every year. This list would include all cases of nystagmus.

I quite well remember the objection to electric lamps at South Moor, but it was on account of the weight of the lamps themselves, and not any objection to the light as such.

I can only conclude that Dr. Percival's figures may refer to one pit only of those included in the South Moor Colliery, and even so, I must disagree with his contention that the number of cases amounted to anything of importance.—I am, etc.,

R. E. INGRAM-JOHNSON.

North Cross, Windsor Forest, Dec. 7th.

#### THE MEDICAL REGISTER: "UNTRACEABLE" PRACTITIONERS.

SIR,—The list published in the SUPPLEMENT of September 11th attracted my attention, but the interest became more personal when I found that my son's name graced it; scanning the list more carefully I discovered the names of five Adelaide residents. It then struck me that perhaps the heading was scarcely justified. "Untraceable" practitioners should mean persons who cannot be traced by any means short of those employed by the greatest talent at Scotland Yard, or by the eminent Mr. Sherlock Holmes. Had the General Medical

Council's officers noted that there were five graduates of the University of Adelaide on the list it might have occurred to them to have communicated with the University itself, or with the Medical Board of South Australia, which annually forwards a copy of the *Register* to the office of the General Medical Council, and made inquiries as to their whereabouts. If the brilliant idea had occurred to them to ring up Tavistock Square they might have ascertained that all five were still regularly paying their subscriptions to the British Medical Association, and receiving their JOURNALS at the usual address. Had they communicated with the editor of the *Medical Directory* they would probably have received similar up-to-date information. Far be it from me to blame the General Medical Council itself—its members have lately been getting into hot water too frequently—but I do think the methods of the office somewhat effete.

One of the "untraceables" told me to-day that he had taken the trouble to register his second reply, as the first might have miscarried.

A Vice-President of our Association, Dr. W. T. Hayward, C.M.G., some years ago had to pay a considerable fine in order to have his name restored to the list; so too had our Inspector-General of Hospitals (Dr. B. H. Morris). Surely no such fee ought to be charged where it is not the unhappy victim's fault that he cannot be traced, but rather the ineffectual methods of the General Medical Council's officers. Of course, if it is necessary to do this to raise sufficient revenue for the Council's purposes it is of no use protesting.—I am, etc.,

October 20th.

YOUR ADELAIDE CORRESPONDENT.

#### RESEARCH IN GENERAL PRACTICE.

SIR,—In your note in the *BRITISH MEDICAL JOURNAL* of November 6th (p. 844) on "Research in general practice," you state that "the great mass of clinical work in this country is done by general practitioners." With this statement of fact we all agree; but later you sorrowfully remark that general practitioners "are not able to take advantage of the opportunities that offer themselves." It is with this latter statement that I find fault. Why are general practitioners unable to take advantage of their opportunities in clinical medicine and surgery?

The answer is the abominable "closed" hospital system that pertains in this erstwhile free country. Our patients are our patients till they develop some symptom or symptoms of interest which can only be elucidated in an institution with further investigation—radiological or biochemical—and once the hospital swallows them up, their family doctor, who is conversant with the early symptoms and maybe with the patient's previous illnesses as well, is generally ignored. His notes of the case are never asked for, and if the patient himself ventures to suggest that Dr. X treated him for such and such a disease, he is sternly requested to forget all that!

Anyone who has done the work of a medical referee under the National Health Insurance Act will agree with me that the "history" of the case, as supplied by the patient's own doctor, is of immense value in helping to arrive at a correct diagnosis; and if this is so in panel practice, why not in general practice?

If followed out intelligently and sympathetically it certainly should be all to the patient's good and help the science of medicine. At present there is not that liaison between the family attendant and the hospital specialist that is so desirable if good results are to be attained. With the present system our patient goes into hospital and thereupon disappears from our ken, to come back weeks or months later with a garbled account of what was found the matter, or, maybe, an obituary notice in the local press leaves us wondering! In other cases, if an operation is required it is the exception for the family doctor to be informed as to when it is to take place. You further say, "The doctor in populous districts will have to train himself to be much more of a specialist than he is at present." How is he to train himself, cut off as he is from direct access to all the more modern methods of investigation, and unable to command the help of laboratory facilities? Your suggestion

of recourse to post-graduate instruction does not fill the bill, since what the general practitioner wants is not instruction but the help of modern methods of investigating disease and the opportunity of watching his patients, either alone or with the help and guidance of the hospital specialist.

And as to the teaching hospitals, they are of the least use to the general practitioner; they take his fees when a student and teach him nothing in return, at least in midwifery, if we are to believe some of our professors in midwifery, and they should know they did their worst on him.

And now, Sir, you want to send us back to the scene of our misfortunes, where we shall be re-instructed in the importance of sending all our patients to the hospital specialist! May I suggest that the British Medical Association turn its attention to serious consideration of this matter and agitate for the freedom of all hospitals to every man or woman on the *Medical Register*, instead of, as at present, bolstering up an effete system of hospital monopoly for the few?—I am, etc.,

VINCENT P. NORMAN, M.D.,  
F.R.C.S.Ed.

Bradford, Nov. 14th.

### CARCINOMA OF THE TONGUE.

SIR,—In the lengthy discussion on carcinoma of the tongue, published in your current issue, there is some talk about sepsis but not much about its prevention. This recalls to my memory that over a quarter of a century ago a distinguished surgical colleague of mine had several deaths in rapid succession from septic pneumonia after removal of the tongue. I suggested that I should prefer being called in before the operation rather than after. I advised that in future cases the patient should have large doses of calcium chloride for the preceding week and an injection of 10 c.cm. of antistreptococcal serum on each of the three days before the operation. Any good antiseptic mouth-wash should be freely used, and for this purpose pure unadulterated whisky, as recommended by Jonathan Hutchinson, was as good as anything else; moreover, if the patient did swallow a little of it there was no danger of poisoning. The operations went on as usual, but there was no more pneumonia.—I am etc.,

London, S.W.1, Dec. 11th.

JAMES BARR.

### Obituary.

C. B. ROSCROW, L.R.C.P., L.R.C.S.Ed.,  
L.R.F.P.S.Glas.,

Late Medical Superintendent, City Mental Hospital,  
Winson Green, Birmingham.

WE regret to record the death of Dr. Cecil Beaumont Roscrow, in a nursing home in Sutton, Surrey, on December 8th, at the age of 56. Dr. Roscrow received his medical education at Edinburgh University, and obtained the diplomas L.R.C.P., L.R.C.S.Ed., L.R.F.P.S.Glas. in 1894. After acting as assistant in general practice to Dr. A. Houldsworth Davis in Sunderland, doing similar work in London, and serving as ship surgeon, he went to the City of Birmingham Mental Hospital at Winson Green as senior assistant medical officer. At the end of eight years' service there under the late Dr. E. B. Whitcombe he succeeded him as medical superintendent, and, as recently as June of this year, retired on pension after twenty-three years' service, and went to live at Sutton with his two sisters.

He had for the last five or six years suffered from diabetes, and this illness influenced him in retiring so soon after he became eligible to do so. A week before he died he developed what appeared to be a large carbuncle in the neck, but this proved to be more extensive than at first thought (involving the spine) and despite two operations he passed away.

Dr. Roscrow was a man of strong character, exceedingly well read and practised in his profession, and extremely conscientious. He had an intense dislike of publicity, and two years ago when persuaded by his chairman to allow

certain press representatives to see over the hospital and "write up" what the hospital was doing in the treatment of general paralysis by malaria, etc., he did so only with great reluctance and on condition that the names of the officers should be kept out. It was characteristic of him, too, that, when the late Dr. Whitcombe died, he made no movement to secure the position to which he was afterwards appointed. He continued the Winson Green tradition of homeliness, and it was always his proud boast that he knew each of his 800 patients by name. He had a ready wit, and this carried him through very often when dealing with an "awkward" patient. He was strict in the supervision of his staff (especially if patients were concerned), but he had the inestimable gift of being able to turn a blind eye to many little delinquencies when he judged that was the proper course. As a result he was loved and very highly respected by his staff and by the patients, who felt they had one they could confide in. He was never very keen on games (although earlier he had played in the hospital cricket team), but he loved to study astronomy, geology, and architecture. Many of his old colleagues will remember his "two in the morning" lectures on the heavens. Although he had travelled abroad a good deal, he became interested, after the war, in the various architectural features of this country, and he motored all over England in his search for architectural knowledge. At Winson Green he greatly increased the giving of "parole" to patients, the sending out on trial of patients, and the payment of money allowances to those out on trial. He made Winson Green one of the earliest of mental hospitals to introduce the "improved breakfast." Other improvements, such as cinema, mechanical spreaders, mixers and so on, were added as soon as brought to his notice.

He was lecturer in mental diseases (clinical) in the University of Birmingham, and a member of the British Medical Association and the Royal Medico-Psychological Association; only last year he was photographed with nearly 70 per cent. of his nursing staff, all of whom had gained the certificate of the Royal Medico-Psychological Association. Dr. Roscrow never married, and he used to quote the late Lord Kitchener in support of his contention that the married man's interest in his work was subordinate to his interest in his home. At any rate he himself made his hospital his whole interest, and it is extremely sad that one who thoroughly deserved a well earned retirement should have been so soon cut off. When he retired last June he was the recipient of many gifts from committee, staff, and patients, and at his funeral on December 10th many representatives from the hospital went to pay a last tribute to his memory.

G. E. S.

Dr. HERBERT DAVID CROOK of Irchester, Northamptonshire, who died suddenly on November 15th, while returning from a visit to a patient, received his medical training at Bristol and Leeds. In 1877 he obtained the diplomas M.R.C.S.Eng. and L.R.C.P.Ed. For some time he held an appointment in Leeds, but on the outbreak of the Russo-Turkish war he joined the Turkish army, and during this campaign saw much active service. Towards the end of it he gave valuable assistance during the small-pox outbreak in Constantinople. On the termination of hostilities he went to South Africa, and was attached to a big-game hunting party for about two years. This expedition carried him well north of the present Rhodesia; during part of it he became acquainted with Selous, in one of whose books he is mentioned. He then settled down in Kimberley, and for many years practised there. While in Kimberley he was medical adviser to some of the large diamond mines, and from time to time took an active part in digging. At this time he was intimate with Dr. Jameson, in whose biography he is mentioned. He went from Kimberley in 1899 to Salisbury in Rhodesia, but had only been there a few months when the Boer war broke out. He immediately volunteered for service and came south, but being unable to get to Kimberley travelled by boat to Capetown. From there he was sent to Johannesburg and put in charge of a large concentration camp. While there, in 1901, he married

Miss Adendorff of Kimberley, and remained in Johannesburg until 1906. He then returned to England, and settled down at Bath, but after four years he migrated to Canada, and took up farming on a large scale in Alberta. In 1921 he again returned to England, and engaged in practice at Irchester, where he was very much beloved and respected by all who came in contact with him. He was a Fellow of the Geographical Society, a member of the British Medical Association, and had just attained the office of president of the Wellingborough Medical Society when he died. He leaves a widow, one son, and two daughters, with whom sincere sympathy is felt.

Dr. SAMUEL CLARKE NOBLE, who died on December 2nd, was probably the oldest medical practitioner in Westmorland. He belonged to a family connected with the medical profession in Westmorland for three generations, and was the son of Dr. James Noble of Kendal. He was born in June, 1837, and received his education at the Kendal Grammar School, Christ's Hospital, and the Middlesex Hospital. He took the diplomas of M.R.C.S.Eng. and L.S.A. in 1859. He carried on his father's practice till 1889, with the exception of some seven years, when he temporarily retired through ill health. Upon the restoration of his health he resumed practice till his final retirement in 1899. Dr. Noble was one of the first members of the staff of the Kendal Hospital, now the Westmorland County Hospital, and was for some years surgeon to the Kendal Prison. He was surgeon major of the 2nd Border Regiment (Volunteers), and during the great war, although nearly 80 years of age, he undertook without remuneration the medical examination of all military recruits in Westmorland. He was a justice of the peace and deputy lieutenant of the county of Westmorland, and a member of the Kendal Division of the British Medical Association.

The following well known foreign medical men have recently died: Professor LUIGI LUCATELLO, rector of the University and director of the medical clinic at Padua; Professor LEO VON LIEBERMANN, professor of hygiene at Budapest; Dr. VIDAL of Hyères, member of the Académie de Médecine and a writer on climatology and infant welfare; Professor BINES, professor of pathology in the Bucarest Faculty of Medicine and director of the anti-rabic institute of Rumania; Professor LE DENTU, honorary professor of surgery at the Paris Faculty of Medicine and member of the Académie de Médecine, aged 85; Dr. CONSELIS DE MOOX, formerly lieutenant-general of the Dutch army medical corps, and inventor of a suture needle and automatic dismountable trephine, aged 72; and Professor H. FRANZ, a Berlin gynaecologist.

## Medico-Legal.

### PROCEEDINGS UNDER AN ACT NOT YET IN FORCE.

The Court of Criminal Appeal (consisting of the Lord Chief Justice, with Salter and Talbot, JJ.) on December 14th allowed the appeal of John Kynaston, retired Lieutenant-Colonel R.A.M.C., against his conviction at the Old Bailey of aiding, abetting, and procuring Rowland Pawsey, whom he was treating for catarrh, to obtain powdered opium, contrary to the Dangerous Drugs Act, 1925, on the ground that a section of that Act provided that it should "come into operation on such date as his Majesty may by Order in Council appoint," and as there had been no such Order the Act had not come into force.

The accused first appeared at the Marlborough Street Police Court on two charges, the second charge being that of falsely describing himself as a recognized licentiate in medicine and surgery by the use of the descriptions "M.R.C.S., L.R.C.P.Lond.," contrary to the Medical Act, 1858, and the stipendiary magistrate adjourned the case on this charge *sine die*, committing him for trial at the Old Bailey on the first charge under the Dangerous Drugs Act. At the Old Bailey the jury, on the direction of the Common Serjeant, found the accused guilty, and a nominal fine of £10 was imposed.

The proceedings at the Marlborough Street Police Court and at the Old Bailey were reported in the BRITISH MEDICAL JOURNAL of October 16th (p. 716) and of November 20th (p. 964).

The appellant, who appeared in person, complained that the prosecution arose as a result of the wrongful removal of his

name from the *Medical Register* by order of the General Medical Council for advertising in 1922—"an offence which has been copied by a number of distinguished men much more than I have ever done."

The Lord Chief Justice said that the point that the appellant's name ought still to be on the *Medical Register* was not open to him. The case started with the fact that he was an unregistered medical man.

The appellant said it was a disgrace for anyone to have a conviction under this Act recorded against him. It was particularly important for him, not only because he was a member of the medical profession in the ordinary acceptance of the term, but also because the Secretary of State had power, on a conviction under the Act, to take away a right he still had to keep a shop and sell medicines and poisons under the Pharmacy Act, 1868. There was nothing in the Dangerous Drugs Acts to prevent an unregistered medical practitioner from properly carrying on his ordinary practice. The object of the Acts was to prevent the improper use of the drugs which came within their regulations. When Section 34 of the Medical Act, 1858, provided that words in any Act of Parliament which imported persons recognized by law as medical practitioners should be construed to mean registered medical practitioners, it was not apprehended that the General Medical Council would assume powers to which it was not entitled.

### An Appeal with no Real Merits.

Mr. H. D. Roome (who appeared for the Director of Public Prosecutions) here intimated to the court that it had only just been brought to his attention that the Dangerous Drugs Act, 1925, under which all the proceedings had progressed, had never been brought into operation by Order in Council, as it had to be.

The Lord Chief Justice: If you had known that this pleasant method of legislation by a hypothetical and contingent Order in Council had been adopted, your conduct of the case would have been somewhat different.

His Lordship, giving the judgement of the court, said the appeal had no real merits, but they were compelled to quash the conviction. By one of those devices referred to in that phrase of Hallam's, which told them that they must "venerate what we cannot presently comprehend in the British Constitution," the Dangerous Drugs Act, 1925, by Section 7, Sub-section 3, provided that the Act "shall come into operation on such date as his Majesty may by Order in Council appoint." There had been no Order in Council, and the Act had therefore not come into force. That prosecution was conducted on the assumption that it had. It thus resembled nothing so much as pulling a bell handle without a bell at the other end.

The appeal was allowed, as stated, and the conviction quashed.

## The Services.

### No. 14 STATIONARY HOSPITAL.

THE annual dinner of the No. 14 Stationary Hospital was held at the Trocadero Restaurant, London, on December 10th. Lieut.-Colonel J. R. Harper, C.B.E., who was in the chair, contributed numerous reminiscences, and many of those present added others. The pleasure of the evening was considerably enhanced by fuller information than usual being available about the present activities of officers who had been on the hospital staff, and in this connexion special thanks were extended to Dr. H. L. Tidy, the organizer of the dinner.

### DEATHS IN THE SERVICES.

Colonel Edmund John Erskine Risk, A.M.S., who died on December 7th, aged 68, received his medical education at St. Bartholomew's Hospital, where he won two scholarships and distinguished himself in rowing. In 1880 he obtained the diplomas M.R.C.S.Eng. and the L.R.C.P. and L.M. Edin. He joined the Army Medical Service in the following year, and served throughout the Egyptian campaign, being present at the battle of Tel-el-Kebir. He was then sent to India, but in 1891 was invalided home with dysentery and malaria; subsequently he served in the Aldershot Command for three years, and in the West Indies for nearly six years. During the Boer war he was in charge of the surgical division at Elandsfontein. After a period of service at Southampton and in Ireland he became senior medical officer at Bultfontein, Orange River Colony; in 1910 he was appointed assistant medical officer to the Northern Command in Ireland, and in the following January commandant and director of studies of the R.A.M. College, Millbank; at the end of the following year his health failed, and in 1913 he retired. He received the medal for Egypt, 1882; the Khedive's star, 1882; and the Victoria medal for the South African war. At his funeral on December 11th the War Office and the Director-General, R.A.M.C., were represented. He leaves a widow and one daughter.

Lieut.-Colonel Robert Alexander Chambers, O.B.E., Indian Medical Service, died of pneumonia at Lahore on November 8th. He was born on October 1st, 1881, and was educated at Edinburgh, where he graduated M.B. and Ch.B., with second class honours, in 1904. He entered the I.M.S. as lieutenant in September, 1906, and became lieutenant-colonel on March 1st, 1926. Most of his service had been spent in civil employ in the Punjab, where he was for some years civil surgeon of Amritsar, and principal of the medical

school at that station; from that post he had recently been transferred to the chair of medicine in Lahore Medical College. He served during the recent great war, in Mesopotamia in 1916 and in 1917-18, and on the North-West frontier in Waziristan in 1917, was mentioned in dispatches in the *London Gazette* of April 15th, 1919, and of January 12th, 1920, and received the O.B.E. on January 1st, 1919.

Brigade Surgeon Lieut.-Colonel Henry James Hazlett, Madras Medical Service (ret.), died in a nursing home at Bournemouth on November 6th, aged 86. He was born at Lurgan, Armagh, and was educated in Dublin, where he took the L.R.C.S.I. and L.K.Q.C.P. in 1866. He entered the I.M.S. as assistant surgeon on April 1st, 1867, became brigade surgeon in March, 1891, and retired in 1897.

Major James Harran, R.A.M.C. (ret.), died in London on October 14th. He was born in Dublin in 1853, and educated at Charing Cross Hospital, where he was medallist in surgery in 1876; he took the L.S.A. in 1877, and the L.R.C.P. and S. Edin. in 1880. He entered the army as surgeon on July 31st, 1880, became surgeon major after twelve years' service, and retired in 1901. After his retirement he lived for some years at Portsmouth.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

IN view of lack of time and threatened opposition, the Government has decided to drop the Mental Deficiency Bill for this session. It passed the House of Lords, was read a second time in the Commons without opposition, and passed through a Committee of the Commons in one day. On December 15th, however, the Prime Minister stated that there seemed little prospect of the measure going through now because so many amendments had been put down. If they were withdrawn he would see what could be done, but otherwise there would be no time. Inquiry showed the Government that the opponents of the bill would not be conciliated. On the Opposition side objection was taken on the ground that it interfered with the liberty of the subject. Conservatives feared that expense would be incurred, and some of the medical members of Parliament were not satisfied with the proposed definition of mental deficiency. The dropping of the bill leaves local authorities powerless to provide for cases of mental deficiency following encephalitis lethargica if the patient is over 16 years of age. There is doubt whether the Ministry of Health will be able to introduce a similar bill next session, as that department is already claiming a large share of the legislative programme.

The Parliamentary Medical Committee has given consideration to the possible business of Parliament in 1927. It looks forward to a bill relating to the Poor Law and local government, and to action on the Royal Commission reports on lunacy and on National Health Insurance. It expressed its satisfaction with the Parliamentary Notes in the *BRITISH MEDICAL JOURNAL* as a summary of business of medical interest transacted in the House of Commons. From other sources it is learnt that the Government has little hope of passing a Lunacy Bill next session.

The University of London Bill was read a third time by the House of Commons on December 7th, and returned with amendments to the House of Lords. The amendments were considered and agreed to on December 13th, and the Births and Deaths Registration Bill was read a third time and passed by the House of Lords on the same day.

Parliament was prorogued on December 15th, the session of 1926 being thus ended. Bills which then awaited the Royal Assent included Merchandise Marks, Electricity, University of London, Births and Deaths Registration, Housing (Rural Workers), Coroners (Protection against Poisoning), and Public Health (Smoke Abatement).

The session of 1927 will probably commence on February 8th.

### Coroners Bill.

A Standing Committee of the House of Commons commenced the examination of the Coroners Bill on December 7th. Mr. Rhys Davies moved an amendment to provide that coroners should have both a medical and a legal qualification; this had been the practice in London for some years, and he could not understand why a single qualification should suffice in towns like Manchester, Liverpool, or Leeds. He did not think the medical qualification alone was quite sufficient for these posts, and he was sure a legal one was insufficient. Captain Hacking (Under Secretary for the Home Office), who was in charge of the bill, said the number of coroners in London was small compared with the number throughout the country—about 300 in all. The choice would be most restricted by insistence on a dual qualification. Large towns

could impose that dual qualification as a condition of appointment if they desired. The amendment was negatived. The clause abolishing franchise coronerships was accepted, as was that relating to the salaries of county and borough coroners, a provision being added that in default of agreement between a borough coroner and the council his salary should be payable at a rate fixed by the Home Secretary. Captain Hacking announced that the Duchy of Lancaster was going to surrender all its franchise coronerships, and that there would soon be none. On the question of summoning a jury in inquests arising out of industrial and traffic accidents and in other stated circumstances, Mr. Lee moved that the word "shall" should be substituted for "may." Captain Hacking said the coroner could always evade the word "shall." Mr. Batey said that in the North of England in cases of fatalities at the pits the men's societies had found it much better to deal with a jury than with a coroner. They might find the coroner absolutely ignorant of pit work. The amendment was withdrawn. On Clause 14, covering the viewing of the body and the issue of a burial order, the wording of a subsection was altered to read:

"Subject to the provisions of any rules made under this Act an order of a coroner authorizing the burial of a body upon which he has decided to hold an inquest may be issued at any time after he has viewed the body."

The clause must work in connexion with the Births and Deaths Registration Bill, and the Home Office thought it should have an opportunity of issuing regulations and rules, rather than lay down something in this bill which might prove unworkable when the other bill became an Act. The Lord Chancellor would make the rules, which would be simple.

On a subsequent clause, Mr. Lee moved that the coroner within whose jurisdiction the accident happened should hold the inquest, and if he deemed it expedient should keep the bodies within that jurisdiction pending the inquest. Mr. Batey said the practice in the North of England for a hundred years had been to take the body of a man killed in a pit straight home, but last year a coroner had refused permission. Captain Hacking said that in many cases it was advantageous that the inquest should not necessarily be held at the place where the accident happened. Several people might be badly injured in a colliery accident, and might be taken to the nearest town where there was a hospital, and if they died there it would not be advisable to remove the bodies to another district to hold the inquest. It might be for the convenience of everyone that the inquest should be held at the place where the bodies were. It would be better that the bodies, if necessary, should be collected together and the inquest held in one place, to save the expense of the coroner and witnesses going from one place to another. The amendment was rejected.

On the clause allowing a coroner to order a *post-mortem* examination in a case where he thought that might show that an inquest might be unnecessary, Sir Richard Luce moved to insert words providing that the coroner should also have power to call for a report from a duly qualified medical practitioner recently in attendance on the deceased if of opinion that this might render an inquest unnecessary. This principle already existed in Scotland, where the Procurator Fiscal obtained a formal written report from the medical practitioner in attendance. A departmental committee had recommended, in 1909, that this feature of the Scottish system should be adopted in England. It was in operation in a coronership in Durham, had never been challenged by the courts, and, according to the coroner concerned, it had halved the number of inquests. Sir Richard Luce added that from personal experience he could say a large number of inquests were needless. Mr. Rhys Davies said the amendment would practically transfer the work of the coroner to the medical practitioner, but he agreed that the certificate of the medical practitioner would be very important in most cases. Dr. Fremantle said the amendment would regularize a practice that had existed. The doctor would simply give the coroner a preliminary report on which he could make up his mind. Captain Hacking said the coroner must accept full responsibility, and could not delegate it to anyone else. It was open at present for the local authority to undertake any reasonable and necessary expenditure in obtaining a report from a doctor. The Durham County Council allowed 10s. 6d. for a report, and there was no reason to believe this was illegal. The doctors, instead of asking for legislation to impose such a fee, should get local authorities to exercise their existing power to provide in schedules for such a fee. Later the backward authorities could be brought into line by the Home Secretary. Mr. Batey supported the amendment as an agent of the Durham Miners' Association, saying that in Durham, where the practice of accepting reports prevailed, there had not been a single complaint. Sir Richard Luce put the case of a patient suffering from heart disease who died suddenly without having seen the doctor for a few weeks. The coroner almost invariably held an inquest, and the doctor was not allowed to give a certificate of the cause of death. At the same time the doctor knew all about the patient, and could give the coroner full information in writing, if asked, which would avoid the need for an inquest. The amendment was defeated by 21 to 7.

On the provision that the coroner might direct a legally qualified medical practitioner to make a report Mr. Smithers moved that this should be a written and signed report on oath. Captain Hacking said the principle of the amendment could be met by enjoining the medical man to report to the coroner in writing. The section was amended to read: "The coroner may move another amendment, desiring that there be nothing underhand in the report." It was held subject to the coroner's orders. Captain Hacking gave an assurance and the amendment was withdrawn. On Clause 22, relating to the power of a coroner to request specially qualified persons to make *post-mortem* and special examinations, Mr. Gates

mored to extend the provision to franchise coroners, but Captain Hacking said the clause applied to franchise coroners. Mr. Leo moved that notice of intention to hold a *post-mortem* examination should be given to the trade union representative of the deceased, and that the union should have the right to be represented at the examination by a qualified medical man. He said that there was a prevailing idea among the families of men who died as the result of accidents that the medical man appointed by the coroner was in some way hostile to their interests. He knew from experience that there was not much ground for that suspicion. There was no difficulty with regard to the coroner knowing who was the trade union representative.

Dr. Fremantle said the medical profession was always glad to have other medical evidence brought in to assure suspicious minds among the lay public that the medical men had done their best and had been accurate. The family ought to be represented, and could, if necessary, notify a trade union representative. Mr. Cape said he thought the intention of the amendment was that the family doctor should be brought to attend the examination. Sir Richard Luce sympathized with the principle of the amendment, but saw considerable difficulties. Employers would also wish to be represented, and most places where *post-mortem* examinations were conducted were not suitable for a large number of persons. Mr. Batey said trade unionists agreed that, while the trade unions should have the right to appoint a medical man, which was essential for compensation purposes, the employer's doctor should be there too. Captain Hacking agreed with this last contention, but said the matter ought to be for the discretion of the coroner. It had been shown that in practice the trade union was notified, and a medical officer appointed by them with the consent of the relatives, as well as the doctor representing the employer's organization. There appeared to be no necessity for putting this into the bill and making it a hard and fast rule. The Home Secretary had power to make rules through the Lord Chancellor. Mr. C. Edwards said he had been a miners' agent in a district where there were two coroners. One in every case informed him; the other refused to give information of inquests. The amendment was rejected by 16 to 10.

Mr. Lee proposed that at the inquest the trade union might call and examine the medical practitioner who had attended the examination on its behalf. Captain Hacking suggested that the committee should have a little more confidence in coroners, and asked to be told of a case where a medical man had attended a coroner's court and had not been called to give evidence. Mr. Cape said medical men had dignity, and would not attend to see whether the coroner would allow them to give evidence. Captain Hacking said that if in practice evidence were not admitted the Home Secretary would cause an inquiry to be made. The amendment was defeated. Discussion was resumed on December 8th. On the proposal that "where a person states upon oath before the coroner that in his belief the death of the deceased was caused partly or entirely by the improper or negligent treatment of a medical practitioner or other person, that medical practitioner or other person shall not be allowed to perform or assist at any *post-mortem* or special examination made for the purposes of the inquest on the deceased," Mr. Smithers moved to make the statement on oath unnecessary and allow the coroner so to act on information received. Captain Hacking said the bill afforded a better procedure in these rare cases. The coroner could request any legally qualified practitioner to make examinations. The oath could be taken before any justice or commissioner, or before the coroner. If it were placed at the discretion of the coroner to say that a certain doctor should be prohibited from performing a *post-mortem* examination, it would be casting a very obvious slur on certain members of the medical profession before any inquiry had been carried out. A person making an accusation against a medical practitioner in the coroner's court would be privileged. The amendment was withdrawn. Sir Richard Luce moved that the medical practitioner to whom objection had been taken should have the right to be present or represented at the examination. He said he had known of no case where a coroner had refused this. The provision that the medical man should not assist or direct at the *post-mortem* examination was put in on account of a case in which a medical man was suspected of murder by poison. He joggled the elbow of the man who was performing the *post-mortem* examination and upset the contents of the stomach so that they could not be examined afterwards. On an appeal by Mr. Rhys Davies, Captain Hacking offered to add the words "but such medical practitioner or other person shall have the right, if he so desires, to be represented at any such *post-mortem* examination." Sir Richard Luce said there might be chemical tests of great importance which a representative should have a right to attend. Captain Hacking said the special examination might last many days, and an analytical test might easily be upset by anyone who desired to do so. If the coroner thought that the medical man impugned should be present he could still attend. Sir Richard Luce withdrew his amendment. On the clause relating to the fees of medical witnesses, Captain Hacking moved that for attendance at any inquest at which no *post-mortem* examination had been made by a practitioner the fee to that practitioner should be one and a half guineas for each day he was required to attend, in place of the inclusive fee of a guinea proposed in the bill. Captain Hacking said he would later suggest a two-guinea fee for a *post-mortem* examination. He thought these fees reasonable. Mr. Cape, while criticizing the proposal, admitted that one guinea was too small a fee for a *post-mortem* examination. Mr. Lee thought it unfair that the medical man who had to travel miles to attend should be paid the same fee as the doctor on the spot. Dr. Fremantle said few doctors were on the spot, and in many cases a whole morning or a whole day of the doctor's time was occupied. The doctor's fees had not been

increased since 1844. Mr. R. Davies asked whether the Government had considered that where the inquest was on a panel patient the doctor would already be paid to the end of the quarter under the National Health Insurance Act. The amendment was accepted by 18 to 2. Captain Hacking then moved that the fee for a *post-mortem* examination without subsequent attendance at the inquest should be two guineas. Sir Richard Luce moved a further amendment to make the fee three guineas; he said that one guinea was a disgraceful fee for performing so important and even dangerous a duty. He supported his view with a quotation from the Departmental Committee of 1903-10. The figure of two guineas was accepted by the Committee. The Committee then agreed that for a *post-mortem* examination followed by attendance at an inquest, the fee should be three guineas for the first day of attendance, and one and a half guineas for each subsequent day on which the medical practitioner is required to attend.

Mr. Rhys Davies asked the Labour members of the Committee to divide against this clause to protest against the way the Government had succumbed to the medical profession. Captain Hacking denied the implication of pressure, and said that the Home Office considered the present fees too small. The clause was added to the bill by 14 to 6. A new clause providing for superannuation on pension of county and borough coroners was added to the bill an amendment to make the pensions contributory being negatived. On a new clause dealing with payments and allowances Sir Richard Luce moved an amendment to provide that medical men should have allowances for distant journeys. Captain Hacking said the legality of paying such allowances had never been challenged. In case of difficulty appeal could be made to the Home Secretary. The amendment was withdrawn. Other proposed new clauses were withdrawn and the bill was reported to the House.

The Report stage of the Coroners (Amendment) Bill was taken on December 13th. Mr. Gates moved a new clause on behalf of the London County Council, providing that whole-time coroners appointed after the passage of the Act should make contributions towards their pensions at the rate of 5 per cent. of their salaries, and that they should be paid pensions calculated according to their length of service. The amendment, however, found no second and so fell through.

Mr. Paling moved to omit Clause 23, which provides for fees to medical witnesses who, at the request of a coroner, make a *post-mortem* examination or attend an inquest. Captain Hacking (Under Secretary for Home Affairs) said that the effect of the amendment would be that medical men would not get any fees at all.

Mr. Rhys Davies said that the amendment was put down as a protest against the manner in which the increase of fees had been made in committee. He asked if there were not some communications between the Home Office and the British Medical Association in the first instance as regarded the amount of fees to be inserted in the bill. Dr. Fremantle denied that there had been any machinations between the Government and the British Medical Association. He had personally come into the House of Commons untrammelled by any responsibility to the British Medical Association. He only supported an increase of medical fees in so far as he thought that it could be justified by the needs of the case from the point of view of the State. In this instance he and others had had a very hard job to convince the representative of the Home Office of the necessity and right of their cause.

Dr. Vernon Davies protested against the attack made on the medical profession by the mover of the amendment. It was entirely unnecessary to make a comparison between doctors and miners. Speeches of that nature were apt to give a very wrong impression. Anything which endangered the good feeling between medical men and their patients was detrimental. If a guinea was a fair fee in 1844, surely at this time there should be some increase. There was a tendency in the Labour party to belittle the medical profession, and the harm that this might do in the country might be very great.

The amendment was negatived.

The Report stage was concluded. On the motion for the third reading Mr. Rhys Davies said that the Labour party had a very high regard for the medical profession.

In reply to questions, Captain Hacking said that the Home Secretary would direct coroners to allow trade union representatives to attend inquests and to allow medical men representing relatives to be present at *post-mortem* examinations.

The third reading was agreed to.

In the House of Lords, on December 14th, the Commons amendments to the Coroners Bill were accepted.

**Acute Poliomyelitis.**—The Minister of Health is advised that the claim made in America that the virus of acute poliomyelitis had been found in the dust of sickrooms has not been confirmed, and that there is no direct evidence that it is transmitted by uncooked food.

**Vaccination and Poliomyelitis.**—On December 10th Mr. Groves asked the Minister of Health why no mention of vaccination was made on the death certificate of the young man of 19, whose name had been privately given to his department, who recently died from acute anterior poliomyelitis fourteen days after vaccination. Mr. N. Chamberlain said the certification of the cause of death rested entirely with the medical practitioner in attendance. Inquiries had, however, been made into the circumstances of the death in question, and he learnt that vaccination was not entered on the death certificate because in the opinion of the certifying practitioner vaccination was not a primary, secondary, or contributory cause of death. In an answer apparently referring to

the same case, Sir K. Wood said that the vaccination of a young man of 19, who recently died about fourteen days after vaccination, was not performed with Government lymph. The case had not been reported to the Committee on Vaccination now sitting.

**Crippled and Physically Defective Children.**—The President of the Board of Education told Mr. R. Morrison, on December 9th, that provision is made for the education of physically defective children at special schools in 263 areas of England and Wales, and in about 140 for the treatment of crippled children by orthopaedic or similar schemes. In about 40 areas no provision had been made, and he would press local authorities to carry out their duties. In 1925 the number of children returned as physically defective within the meaning of the Education Act, 1921, was 142,889. They included those suffering from tuberculosis, and those classed as cripples or as "delicate." Of these, 25,769 attended special schools, 94,332 were at public elementary schools, and 3,857 at other institutions, while 18,931 were not attending any school. Most of the delicate children only required a relatively short period at an open-air school, while the majority of the cripples could be so far benefited by orthopaedic treatment as to make them fit to profit from instruction in ordinary schools. Lord Eustace Percy did not think the country needed better ascertainment and but it was out of harmony with the tendency to suppose that all physically defective children should be taken to special schools.

**Insurance Benefits.**—In a reply, on December 9th, to Mr. Rhys Davies, Mr. Chamberlain said he was aware that a few approved societies in Lancashire and elsewhere were still reluctant to adopt the new scale of fees and conditions of service for dental benefit. The opposition to the new scale was, however, daily growing less as the advantages of the new arrangements drawn up by the Dental Benefit Joint Committee became more fully appreciated. The Public Dental Service Association had called the attention of dentists to a warning notice issued by the Dental Board against anything in the nature of canvassing by or on behalf of dentists with a view to securing work by an offer to accept fees below those of the new agreed scale. Mr. Chamberlain added that he saw no need to take action, as an agreement had already been reached. Answering Mr. Thurtle on the same day, Mr. Chamberlain said the money paid by way of contributions to the health insurance scheme in England and Wales for the seven years from January 1st, 1919, to December 31st, 1925, was £154,000,000. Of £143,000,000 spent on benefits in England and Wales during the same period, £86,000,000 represented amounts actually paid out to insured persons by way of benefits, and £57,000,000 the cost of medical benefit provided for them through insurance committees.

**Spahlinger Treatment of Cattle.**—On December 13th Mr. Hurd asked the Minister of Agriculture if his department had received a copy of the report of the Geneva State veterinary surgeons recording the success, which they stated to be beyond all hopes, of the Spahlinger tests, now completed there, with antituberculosis vaccine on cattle, and whether he contemplated any further steps to estimate the value of these reported results. Mr. Guinness replied that the Ministry's knowledge of the tests of M. Spahlinger's vaccine which had recently taken place in Switzerland was limited to accounts published in the press. In 1924 a committee was formed under the chairmanship of Commander Bayley, R.N., which included prominent agriculturists, doctors, and veterinary surgeons. This committee had formed complete plans for experimental trial of the vaccine, but was unable to obtain any vaccine from M. Spahlinger, and therefore the matter dropped. He understood that the committee was still in being, but he was unable to say whether it would be prepared again to undertake the trial of this vaccine.

**Research in East Africa.**—In the debate on the second reading of the Palestine and East Africa Loans (Guarantee) Bill on December 7th, Dr. Haden Guest said that the House should have more particulars concerning the proposed expenditure of £100,000 on research into native welfare. Every time railways were built or public health improved in Africa native habits were uprooted and native traditions upset. Statistics showed that from 1901 to 1921 there had been a decrease in the population of Uganda and Kenya, a slight increase in Somaliland, considerable increase in the Sudan, and a steady increase in Nigeria. Where the Government had been best the social conditions were best, and there was a steady increase in population. This bill would bring on a state of things in which the population of tropical Africa might largely increase. Mr. Ormsby-Gore said that in some areas of Africa the British had stopped the tribal wars, had broken up the old customs, but the males were doing absolutely nothing. The sooner that came to an end the better. Mr. Ormsby-Gore added that the Colonial Secretary and he would get every penny they could to promote scientific research within the Empire. He himself had found glaring instances of the shortcomings of his fellow-countrymen in research. He had to preach to very unconverted people, and would continue to do so. Research meant not merely investigation of the diseases of plants, animals, and human beings, but more fundamental research into economic and social relations. A much larger staff for research was needed. The bill was read a second time. It passed through Committee on December 9th, and through Report stage on December 10th. The bill was read a third time in the House of Commons on December 13th, and was afterwards read the first time in the House of Lords.

**Experiments on Dogs.**—Captain Hacking informed Sir R. Gower, on December 13th, that 1,147 dogs had been used for experimental purposes at University College, London, during 1925 and 1926. Of these, 21 were used for demonstrations before students.

Section 3 of the Act laid it down that experiments for this purpose could only be performed if a certificate was given by two of the scientific authorities specified in the Act that the experiments were absolutely necessary for the due instruction of the students with a view to their acquiring physiological knowledge or knowledge which would be useful to them for saving or prolonging life or alleviating suffering. Such experiments were required to be performed under anaesthetics, and the animals must be killed before recovering consciousness. All but 28 of the total number of animals were kept under anaesthetics during the whole of the experiment and destroyed before recovering from the anaesthetic. On December 14th Captain Hacking told Sir R. Gower that since January 1st, sixteen dogs had been used for experiment at University College, and five at the Brown Institution. He could not undertake to give details of individual experiments, but the object of the experiments was in seven cases the investigation of dental diseases, in five insulin research, in four investigation of diseases of the tonsils, and in five investigation of the relation of the gall bladder to intestinal diseases. The Act required that before any experiment could be performed which involved keeping the animal alive after it recovered from the anaesthetic, a certificate must be given by two of the scientific authorities mentioned in the Act to the effect that killing the animal before it so recovered would necessarily frustrate the object of the experiment; and further, that before any such experiment was performed on a cat or dog an additional certificate must be given by two of the same scientific authorities that for specified reasons the object of the experiment would be necessarily frustrated unless it was performed on an animal similar in constitution and habits to a cat or dog and that no other animal was available for such experiment. These certificates were duly given in each of the cases mentioned above.

#### Notes in Brief.

A proposal for the compulsory registration of charities on the principle of the War Charities Act is being considered by an inter-departmental committee.

In 1925 five persons in the pottery trade died from lead poisoning; their average age was 58. Corresponding figures for 1924 were 18 and 52.

The Minister of Health suggests that local authorities during the first part of 1927 should abstain from the use of foodstuffs. The Public Health (Preservatives in Food) Bill, which would make it a punishable offence to use any foodstuffs in which reasonable attempts had been made to preserve them, is being considered.

Of 2,000 steel houses in Scotland for which Parliament has made a special grant, 1,086 had been completed at the end of November, and 906 were building. Favourable reports had been received from tenants who had lived in steel houses both summer and winter.

The Government is considering the co-ordination of the research work carried on by or under it in this country.

The Minister of Health doubts whether there is sufficient agreement on facts or conclusions to justify the introduction of legislation making it a punishable offence to marry or connive at the marriage of any person certified as a mental defective.

The total number of applications for old age pensions received in the six months to November 1st, 1926, in England, Wales, and Scotland was 216,814.

The Foot-and-Mouth Disease Research Committee has presented a second progress report, which is being printed.

No milk is being brought from Ireland into England and Wales.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

DR. W. E. DIXON, F.R.S., has been re-elected assessor to the Regius Professor of Physic for the current academical year.

At a congregation held on December 10th the following medical degrees were conferred:

M.B., B.Ch.—J. Holmes, E. W. P. Thomas, W. Richards.  
M.B.—C. J. P. Grosvenor, C. G. Taylor.  
B.Ch.—W. S. Hunt.

### UNIVERSITY OF LONDON.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—\*A. C. Dalzell, \*L. Harleston, \*M. Milman, \*S. H. Steele (University Medal), Dorothy R. Adams, C. E. Allen, H. Awroun, S. C. Bakke, J. R. Beagle, S. A. Beards, L. F. Beeble, E. H. J. Berry, E. H. D. Bowie, R. J. Cann, Rose A. Carter, Evangeline A. Clark, J. S. Coleman, H. A. Cooper, A. O. Counsell, Anne A. Craig, S. S. Cruden, H. J. Davies, Muriel Davies, Doris L. Delittle, J. C. G. Dickinson, J. D. Durand, Elaine G. Earenger, D. C. Fairbairn, M. Fishman, W. Fletcher-Barrett, W. F. Galsford, S. C. Gavne, P. L. Goitein, Minnie Gordon, C. H. Greenfield, J. I. Griffiths, R. D. Gross, L. W. Hale, J. G. Hamilton, E. P. Hare, R. B. Hawes, W. E. Heath, Frances M. Henton, J. C. Howatson, N. G. Hill, F. D. M. Hocking, D. P. Holmes, B. B. Hosford, D. V. Hubble, Amelia M. Ison, C. James, H. N. James, Iorwerth H. Jones, R. O. Jones, Isabel M. Jordan, Gladys Kay, Greta M. Langdon, R. H. Leigh, R. H. Little, G. K. Loveday, Elsie

Erin, Margaret B. MacDonald, N. W. MacKilloch, Evelyn T. D. MacLellan, D. H. MacLeod, I. McPherson, Dorothy H. Marling, Mary A. Marshall, S. K. Montgomery, J. O. Morgan, Dorothy D. Neale, G. J. V. Nelson, G. A. H. Norman, H. L. O. Odershaw, Catherine E. Orr-Ewing, Evelyn M. Pakeman, W. E. Parry, O. E. Parsons, A. D. Pege, G. E. O. Peirce, L. M. J. R. Pilot, I. Price, Henrietta Procter, Muriel F. Proust, D. M. Pryce, Bertina M. Rix, L. H. Savin, J. W. Schabert, J. A. Scerch, E. C. Seward, Mary M. Shillo, A. S. Simpson, A. I. D. Smith, W. E. Snell, I. P. Spurrell, E. F. Stead, Edith A. Straker, S. V. Stroud, D. L. Thomas, J. D. B. Thomas, O. G. Tippet, J. R. Tree, Betty C. Waters, Elsie M. Webb, A. S. Wesson, Violet M. Weston, L. A. White, Doris Williams, Jane C. Williams, Emily A. C. Wilson, H. F. Wilson, J. T. Wybourn.

\* Honours. † Distinguished in Medicine. ‡ Distinguished in Pathology.  
§ Distinguished in Surgery. || Distinguished in Midwifery.

The following students have passed in one of the two groups of subjects:

Group I.—D. E. Barton, Doris D. Brown, Isabella M. G. Butler, Irene F. Callender, T. E. Davies, A. E. de Charaz, Jean M. Dollar, J. Gabe, A. C. Hancock, Lynette Hemmatt, Mary H. McC. Hugb, R. M. Jones, Ellen M. King, Miriam A. Lawson, W. Leslie, A. H. Levers, M. F. B. Lynch, Barbara H. Mitchell, Doris Reynolds, Elsie D. Rogers, E. S. Rudzsky, Margaret V. Smit, H. S. Townsend.  
Group II.—W. A. Ball, A. L. Banks, R. E. Barrett, Rhoda M. P. Bond, D. G. Bond, D. A. Brigg, Helen M. Browne, M. R. Burke, A. L. Cobby, D. C. MacC, Eileen J. Evans, Leonora S. Evans, B. W. Goldstone, D. P. Gray, H. P. Hisecock, L. Holmes, J. G. Kingsbury, E. D. Lawrence, Joan L. Lush, A. C. Macleod, C. W. Marshall, E. D. Marshall, J. P. Payne, Alice J. Robinson, L. E. Sayer, Mary C. Tugman, Alice A. Wilkinson, H. K.

### UNIVERSITY OF LIVERPOOL.

Major W. Scott Patton, I.M.S.(ret.), lecturer in medical entomology in the University of Edinburgh, has been appointed to the Dutton Memorial Chair of Entomology in the School of Tropical Medicine of the University of Liverpool, in succession to Professor Robert Newstead, F.R.S., retired.

### UNIVERSITY OF ST. ANDREWS.

A MEETING of the University Court was held on December 3rd. The court concurred with the University of Edinburgh in nominating Dr. R. W. Johnstone (Professor of Midwifery, University of Edinburgh) to be the representative of the two universities on the Central Council of the Midwives Board for Scotland, in succession to Professor Watson.

The appointment of Dr. Annie Fulton as an instructor in relation to the advanced medical school (in succession to Dr. Andrewina Laidlaw) was agreed to.

Principal Mackay was reappointed the representative on the General Medical Council for five years from January 7th next.

### UNIVERSITY OF DUBLIN.

At the first winter commencements in Michaelmas term held in the theatre of Trinity College, on December 10th, the following degrees and licences in medicine were conferred:

M.D.—J. A. Acheson, M. Hawley, J. C. J. M'Entee.  
M.B., B.Ch., B.A.O.—E. W. Bingham, A. J. Conlin, Gladys L. Craig, Margaret E. S. Deane-Oliver, Margaret H. Donaldson, E. P. N. M. Early, H. A. Ferguson, E. H. Harle, R. A. J. Holmes-Jevers, V. G. Horan, J. Johnston, M. L. McCarty, E. G. Montgomery, A. E. A. O'Byrne, J. B. Patrick, Rachel E. Porter, J. Quigley, D. A. O'G. O'Sullivan, Stella C. Ross, A. Sachs, J. C. T. Sanctuary, Nuala M. Smith, L. B. Somerville-Large, V. St. G. Vaughan, C. F. M. Wilson, Annette R. Woolf-Martin.

LICENCE IN MEDICINE, SURGERY, AND OBSTETRICS.—A. N. B. Oabert.

### NATIONAL UNIVERSITY OF IRELAND.

At the meeting of the Senate on December 10th Dr. Alexander Anderson, D.Sc., LL.D., President of University College, Galway, was elected Vice-Chancellor and Dr. Denis J. Coffey, LL.D., M.B., President of University College, Dublin, was elected one of the three pro-Vice-Chancellors of the University. The Senate decided that the degree of D.Sc.(Public Health) should be awarded to William D. O'Kelly, M.D., D.P.H., University College, Dublin, upon published works lodged by him. A report from the outgoing Vice-Chancellor, Dr. Denis Coffey, as representative of the University on the General Medical Council was approved.

### UNIVERSITY OF SYDNEY.

The following appointments are announced by the Senate:

Professor of Psychiatry: William S. Dawson, M.A., M.D.Oxf., M.R.C.P.Lond., senior assistant, Maudsley Hospital, Denmark Hill, London, vice Professor Sir John Macpherson. Lecturer in Pharmacy: Mr. Horace Finmore, B.Sc., F.I.C., F.C.S., of Guy's Hospital Medical School, London, vice Mr. S. H. Stroud. Lecturer in Chemistry: Dr. Thomas Iredale, of Armstrong College, Newcastle-on-Tyne, vice Associate Professor J. A. Schofield.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council meeting was held on December 9th, when the President, Sir Berkeley Moynihan, Bt., was in the chair.

#### Representation of Members.

The resolution carried at the annual meeting of Fellows and Members asking the Council to take a postal vote of Fellows and

Members on the question of admitting Members to direct representation on the Council of the College was referred to a committee for consideration.

#### Court of Examiners.

Mr. E. Rock Carling, surgeon to the Westminster Hospital, Mr. A. E. Webb-Johnson, surgeon to the Middlesex Hospital, and Mr. C. Frankau, surgeon to St. George's Hospital, were elected members of the Court of Examiners.

Mr. O. H. Howkins, dental surgeon to the Birmingham Dental Hospital, was elected a member of the Board of Examiners in Dental Surgery.

#### Diplomas and Licences.

The report of the Court of Examiners stated that of the 101 candidates at the Fellowship Examination 70 were rejected and 31 passed. Diplomas of Fellowship were granted to the following 27 candidates; the other four successful candidates (R. A. Brews, C. I. N. Morgan, F. T. Ridley, and A. J. Wrigley) have not yet complied with the regulations.

J. S. Bowland, P. B. Kittel, R. C. Brown, E. A. Coldrey, P. R. Hawe, B. I. Levy, A. L. P. Jeffery, N. Asherson, W. E. Barrie-Adamshead, L. H. Savin, V. W. Dix, K. W. Horne, A. O. King, K. O. Parsons, S. J. H. Grith, Bobb, P. Mahas, T. S. M. Barnett, A. Harris, P. Kiley, L. D'A. McCrea, P. A. Mitchell, I. G. Sacks.

Diplomas of membership were conferred upon A. C. Jepson, P. N. Ishiri, and L. A. Richardson.

Licences in Dental Surgery were conferred upon 83 candidates.

#### Appointment of Representatives.

Sir Berkeley Moynihan was reappointed a representative of the College on the Court of Governors of the University of Birmingham.

Mr. Victor Bonney was appointed a representative of the College on the Central Council for District Nursing in London.

### ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

The following have been admitted Fellows of the Faculty:

W. C. Gray, I.M.S., R. C. Lal, I.M.S., A. S. M. Macgregor, O.B.E., B. T. Rae, J. Rutherford.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At a special business meeting of the Fellows, held on December 10th, the President admitted to the licences in medicine and midwifery of the College the following who had been successful at the winter examinations: the conjoint scheme with the Royal College.

T. A. Carabier, W. Monnelly, Patricia O'Kane, D. L. Traut, T. Walshe.

### ROYAL COLLEGE OF SURGEONS OF IRELAND.

Mr. ADAMS A. M'CONNELL, M.B., B.Ch., B.A.O., F.R.C.S.I., has been appointed Professor of Surgery.

## Medical News.

THE proposed pension scheme for hospital officers and nurses, to which we referred on August 14th (p. 321), has now been accepted by eighty-eight London hospitals, comprising 11,579 beds. Steps are being taken to obtain quotations from insurance companies for the various benefits contemplated. It is expected that these will have been received by the end of the first month or six weeks of next year, and that the scheme will be ready for starting shortly afterwards. A memorandum dealing with the present position of the scheme has been issued by the provisional council, and may be obtained from the printer, G. Barber, 23, Farnival Street, E.C.4.

THE Livery dinner of the Society of Apothecaries of London was held at Apothecaries' Hall on December 14th under the chairmanship of the Master, Dr. Alfred Hepburn, and was made the occasion of the presentation to Professor W. E. Dixon, M.D., F.R.S., of the first award of the Society of Apothecaries' gold medal. On the obverse of this medal is a finely moulded bust of Galen, and on the reverse Science, represented by a female figure, is shown instructing a youth in the right use of herbs: an apothecary's oven is also indicated, and the insignia of Aesculapius. The toast of the Royal Colleges was proposed by the senior warden, Dr. R. Whitelock Statham, and was acknowledged by Sir John Rose Bradford and Sir D'Arcy Power. The junior warden, Lieut.-Colonel C. T. Samman, R.A.M.C.(ret.), proposed the health of the guests, and Mr. Arthur Denman, clerk of assize for the South Western Circuit, responded.

THE Prince of Wales presided, on December 14th, at the distribution meeting of the general council of King Edward's Hospital Fund for London. It was announced that the sum for distribution was £284,750, including a special grant of £39,750 from the Wells estate. Further particulars will appear in a later issue.

THE house and library of the Royal Society of Medicine will be closed from Thursday, December 23rd, to Tuesday, December 28th, both days inclusive.

THE Royal Society of Medicine will hold its next social evening at 1, Wimpole Street, Cavendish Square, on Monday, January 17th. At 8.30 p.m. the guests will be received by the President and Lady Berry, and at 9.30 Professor A. V. Sheen, C.B.E., M.S., will give a short address, entitled "Medicine in Ancient Greece," with lantern illustrations. The library will be open, and various objects of interest will be exhibited. Music and light refreshments.

THE Fellowship of Medicine announces that from January 10th to 22nd the Prince of Wales's General Hospital will hold an intensive course in medicine, surgery, and the specialties. A fortnight's course in diseases of children by the Royal Free Hospital and the Children's Clinic will start on January 10th. From January 11th to February 5th there will be a series of lecture demonstrations on psychological medicine, on Tuesdays and Saturdays, at 11 a.m., at the Bethlem Royal Hospital. From January 17th to 29th an intensive course in cardiology (limited to 20) will be held at the National Hospital for Diseases of the Heart. Courses in practical obstetrics can be arranged at Queen Charlotte's Hospital to last two weeks or a month. Each week the City of London Maternity Hospital holds a course in obstetrics and child welfare, personal application for which must be made to the office of the Fellowship of Medicine. The Fellowship can also arrange for clinical assistantships at the Samaritan Hospital. The series of lectures on emergencies in medicine and surgery will be continued from January 27th; demonstrations in clinical surgery and ophthalmology will also be resumed in January. Copies of all syllabuses of the special courses and the programme of the general course of work can be obtained from the Secretary of the Fellowship, 1, Wimpole Street, W.1.

A DISCUSSION on the inebriate woman will be opened by Commissioner Adelaide Cox, C.B.E., of the Women's Social Service Department of the Salvation Army, at the meeting of the Society for the Study of Inebriety to be held at 11, Chandos Street, Cavendish Square, W., on Tuesday, January 11th, at 4 p.m.

TWO sets of post-graduate courses have been arranged at the Royal Northern Hospital, Holloway Road, N. 7. The first course is open to all medical practitioners free of charge, and will consist of weekly lectures or demonstrations by members of the staff on Tuesdays, at 3.15 p.m., commencing January 4th, 1927, and intensive courses, each of one week's duration, to be held in February, May, and October. The second course on recent advances in medicine is suitable for the M.R.C.P. and other higher examinations. Full particulars can be obtained on application to Dr. E. G. B. Calvert, Dean, Royal Northern Hospital, Holloway Road, N. 7.

THE Old Epsomian Club held its forty-seventh annual meeting and dinner on December 9th at the Trocadero Restaurant, the President, Mr. H. A. T. Fairbank, in the chair. In reply to the toast, "Floreat Epsomia," proposed by him, the headmaster gave an account of the successes of the College during the year in all departments. He referred particularly to the success in obtaining guarantors and subscribers towards the £3,000 required to build a new cricket pavilion. The toast of "The Visitors" was proposed by the Right Hon. Sir H. J. Mackinder in a humorous speech, and Dr. G. E. Waugh, proposing the health of the chairman, referred particularly to Mr. Fairbank's distinguished services during the war.

THE seventh Latin-American Medical Congress will be held at Mexico on March 15th, 1927.

**Tuberculous Disease**, which is, to quote the sub-title, "a study in continuous and quasi-continuous temperature records of man and animals in health and disease." This is a reissue of papers by the late Sir German Sims Woodhead and Dr. P. C. Varrier-Jones, together with the results of Dr. Varrier-Jones's further experiences at Papworth. It has been printed and bound, and will be published by the consumptive ex-patients in the printing department of the Papworth Village Settlement.

LORD D'ABERNON, G.C.M.G., has accepted the chairmanship of the Industrial Fatigue Research Board, to which he has been appointed by the Medical Research Council. Mr. William Graham, M.P., has relinquished the chairmanship under the pressure of other public work, but will remain a member.

THE Canadian Department of Health at Ottawa has issued in pamphlet form a list of the public, private, and Red Cross hospitals of Canada. The institutions are arranged according to the various provinces, and the number of general and maternity beds is given in each case. A map of the Dominion is appended showing the distribution of hospitals in each province. Copies of the pamphlet are obtainable from the department.

THE Bureau of the Far East at Singapore reports that during the week ending October 30th there were 9 cases of plague with 5 deaths, 6 cases of cholera with 2 deaths, and 33 cases of small-pox with 5 deaths; during the week ending November 6th there were 18 cases of plague with 10 deaths, 32 cases of cholera with 22 deaths, and 26 cases of small-pox with 6 deaths; and during the week ending November 13th 76 cases of cholera with 38 deaths and 26 cases of small-pox with 6 deaths.

THE centenary of the Ludwig Maximilian University at Munich, which counted among its members Liebig, Pettenkofer, and Röntgen, was celebrated last month.

UNDER the will of the late Mr. George Paterson Walker the Kilmarnock Infirmary received £2,000. The late Captain Athelstane Robert Price has bequeathed £1,000 each to the Royal Salop Infirmary and to the Shrewsbury Eye, Ear, and Throat Hospital for Shropshire and Wales.

THAT small-pox is still occasionally as virulent as ever is shown by the fact that out of 1,908 cases at Rio de Janeiro from January 1st to August 14th 1925 died—a mortality of 44.2 per cent.

THE Health Organization of the League of Nations has published in two volumes the Public Health Code of the Kingdom of Belgium, printed throughout in French. The first volume, of 388 pages, comprises the laws and regulation concerning hygiene and public health, the second, of 132 pages those relating to the practice of medicine.

PROFESSOR GALLEMAERTS of Brussels has been nominated president for 1927 of the Royal Academy of Medicine of Belgium, with Professors Léon Frédéricq and Malvoz of Liège as vice-presidents.

BY a recent enactment the use of alcoholic liquors has been forbidden to persons under 18 years of age in all the college and educational establishments throughout Italy.

DR. CHAGAS, professor at the faculty of medicine of Rio de Janeiro, and Dr. Medin, professor at the faculty of medicine of Stockholm, have recently been made doctors *honoris causa* of the Paris faculty of medicine.

THE first congress of the Latin medical press, which was to have been held at Paris in October, has been postponed to April. The chairman of the executive committee is Dr. M. Loeper, president of the Association of the French Medical Press. Further information can be obtained from the general secretary, Dr. L. M. Pierra, 12 Rue de Babylone, Paris VIIe.

THE subjects to be discussed at the eighteenth congress of the Italian Society of Psychiatry, which is to be held at Trent next year, will include endocranial tension and its relation to neuroses and psychoses, changes in the structure of the cortical cells in mental disease, and the civil capacity of mental patients and abnormal persons according to present legislation.

IN reply to a request for information from the Union of School Hygiene Societies of Japan the London Education Committee has expressed its opinion that it would be advantageous if the International Congress of School Hygiene were revived and arrangements made for a meeting at as early a date as practicable. The congress has met four times since 1904; arrangements made for a fifth meeting in Brussels in 1916 were broken off on account of the war.

WE have received a copy of *Boletín del Departamento de Salubridad Pública*, a quarterly publication issued by the Mexican Department of Public Health. In addition to an account of the work of the department and the various services under its control, the bulletin contains statistics of deaths from all causes in the City of Mexico, with separate tables for infectious diseases and the causes of intrauterine death.

UNDER the title *Dust of Gold* an account of the work of the Church of England Zenana Missionary Society among the blind and deaf of India, China, and Ceylon has been written by Mrs. M. E. Hume Griffith. A list is given of five schools for the deaf and blind which are supported by the society, and accommodate 489 children. The booklet is well illustrated, and may be obtained from the society, 27, Chancery Lane, W.C.2, price 1s.

WE have received the twelfth and thirteenth volumes of the *Archivio Italiano di Chirurgia*, which contain eighty papers on various subjects of surgical interest, dedicated to the Senator Professor Antonio Carle of Turin by his friends and pupils in commemoration of his thirty years of teaching.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal*, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are *MUSEUM 2251, 2262, 2263, and 2264* (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR of the *British Medical Journal*, *Antiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediverna Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Brilliant, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### CARBON DIOXIDE IN RESPIRABLE AIR.

"RESPIRATOR" asks for information about the percentage of carbon dioxide in air which can be breathed without apparent harm—as, for example, in submarines.

#### PTYALISM.

DR. W. ERLE FARMER (Birmingham) asks for suggestions for the treatment of a patient from exsialation to such an extent that saliva pours out. There is no dental sepsis or any other obvious cause.

#### ULTRA-VIOLET LIGHT IN RAYNAUD'S DISEASE.

The question Dr. Sidney Matthews (Crawley) desired to put was misunderstood (p. 1057). He wished to know whether ultra-violet light had been used in the treatment of Raynaud's disease. He has a case of the second degree under his treatment at the present time, but has not advised ultra-violet treatment.

#### PUS CELLS IN URINE.

"A. R. L." writes: Is the presence of a few pus cells in the urine significant of very much? I have a patient in whose urine there are some pus cells and epithelial debris; clinically there is nothing at all the matter with my patient beyond a little dental trouble, with, possibly, the existence of a focus or two of pus at the roots of old stumps, which are being cleared out.

#### THE DETERMINATION OF SEX.

DR. A. J. COLBY TINSLEY (Hastings) writes: Dr. McConnell Boyce (November 13th, p. 918) gives his opinion that when conception takes place prior to a menstrual period a male child results, and a female when conception is after a period. It is rather remarkable that Mrs. Monteith Erskine as a result of her observations should have arrived at exactly the opposite conclusion—namely, normal male conceptions occur between the eighth and fifteenth day counting from the very beginning of the period, and female conceptions from twenty-first to twenty-eighth day (see *Sex at Choice*, Chap. IX and XI). It is not my intention to recapitulate Mrs. Erskine's arguments because they are accessible to the medical profession and the general public. I should, however, like to submit two propositions: either (a) one of the above-mentioned observers must be mistaken, or (b) the riddle of sex is still unsolved.

DR. H. W. EVANS (Brundall, Norwich) writes: I can endorse Dr. Boyce's opinion that conception immediately preceding a menstrual period results in a male child. A patient of mine, having three daughters and desiring a son, took precautions that insemination only occurred during this time. His care was rewarded by the birth of a boy. As Dr. Boyce says, it is a fact worth knowing, and, though I can only quote this one case, I think it worth recording in support of his theory.

#### TREATMENT OF LEUCODERMA.

DR. RAWAL CHAND SURI (Rawalpindi) writes with reference to the inquiry by Dr. D. S. Puttanna (July 31st, p. 235) about treatment of a girl, aged 7, suffering from patches of leucoderma on the face and extremities. Dr. Suri suggests that iodine tincture should be painted twice a day on the spots, and thinks this is effective in about a week's time in early cases. Persistent and deep infections may be treated with a saturated solution of sodium thiosulphate.

#### TINNITUS IN MENIÈRE'S DISEASE.

MR. F. FRANK STUMM, M.Ch. (Ear and Throat Clinic, Leigh, Lancashire), writes: Menière's disease is a generic term which conveys no definite information. If "H. S." (*BRITISH MEDICAL JOURNAL*, November 27th, p. 1027) is sure that his patient's tinnitus is not tubo-tympenic, oto-sclerotic, nor retro-labyrinthine in origin, he should try half-grain doses of quinine sulphate thrice daily for a month, and if these fail, 3-grain doses of sodium salicylate as frequently for the same period. Both of these drugs have lulled labyrinthine tinnitus. No case, whatever its apparent background, should be regarded as hopeless until the tubes have been investigated by the electric endoscope of Holmes and dilated by the Eustachian bougies. True organic stricture of the Eustachian tube is so rare as to be a curiosity, but catarrhal hyperplasia (non-organic stricture) is not only common but frequently overlooked, and may cause a high degree of deafness, vertigo, tinnitus, even spontaneous nystagmus—in fact, all the symptoms of Menière's complex except the vomiting. It may be cured by a correct Eustachian catheter technique. The drugs mentioned by "H. S." are of value only where tinnitus depends upon systemic blood pressure abnormalities. In every case of the so-called Menière's disease there is the possibility of a tumour of the nervus acusticus in or near the porus internus.

DR. A. BETTS TAPLIN (Liverpool) writes in reply to "H. T." regarding nervous retching, also to "H. S." with reference to tinnitus in Menière's disease, to say that both these troubles can be successfully dealt with by a course of suggestive treatment.

"D. M." writes in reply to "H. S.": As a personal sufferer I have found Dr. Dan McKenzie's paragraphs on treatment in his *Diseases of the Throat, Nose, and Ear* most helpful. He divides all cases into three groups: (1) those with high blood pressure; (2) those with low blood pressure; (3) toxic cases. For the second group, in which I classed myself with a moderate blood pressure, he advises extractum ergot liq. 20 minims three times a day. Since I started this treatment I have undoubtedly had more freedom from the noises in the ear, as well as from the sensation of not far distant giddiness. At present I am taking 3-grain tablets, sometimes two in the morning and one three times a day and variably. I am satisfied that sodium bromide, which used to help me in 1909 at the age of 34, does not now do so, but increases the tendency to giddiness.

#### INCOME TAX.

##### Motor Car Transactions.

"MOTORS" has owned and used two cars for over six years. Car A was bought in 1920 for £775 and sold in 1926 for £70, a second-hand car being bought for £615; car B was bought in 1920 for £632 and is still in use.

It has to be borne in mind that, apart from the "depreciation" allowance, there is no income tax allowance for lost capital as such; the deduction that can be claimed is for the out-of-pocket cost of replacement. When car A was replaced the actual amount expended was £615-£70=£545, and "Motors" cannot legally deduct more. So far as car B is concerned the authorities are strictly correct in computing the loss by wear and tear during the year according to the value of the car at the beginning of that year. Our correspondent should remember that when car B is replaced he can claim the "obsolescence" allowance, calculating it at the net cost of replacement less the amount of the depreciation allowances he has actually received in respect of that car. When that allowance has been claimed in due course the disparity between the total loss of capital and the total amount allowed for tax purposes will not be so serious as it seems to be at present. The forthcoming change from the three years' average will apparently work adversely, but perhaps our correspondent would like to send us the figures when preparing his 1927-28 return; in that case he should state the date in each year at which he closes his accounts.

### LETTERS, NOTES, ETC.

#### A MEDICAL ASPECT OF MINERS' SHORTER HOURS.

DR. NOEL H. M. BURKE (Orpington) writes: Does not Dr. Bushnell's interpretation of figures (December 11th, p. 1145) contain a fallacy? He argues in terms of accidents per 100,000 miners employed to show that reduction of hours leads to reduction of accidents. If 100,000 men work for seven hours a day there are 100,000 fewer man-hours of exposure to risk of accident than when eight hours are worked. This time factor should be allowed for.

#### SEBACEOUS CYSTS: A POINT IN DIAGNOSIS.

MR. A. P. BEUTWISTLE, M.B., F.R.C.S.Ed., writes to draw attention to the peculiar sudden blanching of the field of operation when the wall of a sebaceous cyst is properly injected with adrenaline-novocain solution. "As I have never known it to occur with dermoids (or lipomata), it is a point in differential diagnosis, when both cysts may occur, such as at the angles of parietal bone and orbit, or in the neck, where dermoids of thyroglossal or branchial origin may be encountered. Incidentally such blanching is of the greatest service in localizing the injection and rendering the field anaesthetic."

## DIFFICULT OCCIPITO-POSTERIOR PRESENTATIONS.

DR. JOHN T. MACLACHLAN (Glasgow) writes: These presentations often worry young practitioners, who find that the head, after it has come well down to the ischial spines, obstinately stays there. Teachers advise patience and caution, as rotation is said to occur in the vast majority of cases of persistent occipital presentations. The chief difficulty appears to be that the head is not properly flexed, and its long diameter thrown across the pelvis. Young practitioners in such cases should be warned against pushing the head back and turning. I have known of two deaths brought about in this way from rupture of the uterus. I have usually succeeded by applying forceps and extracting slowly. I have known one or two young practitioners fail, as the forceps kept sliding off the head. This can be overcome, in my experience, by, in the first instance, pulling towards the sacrum, before making the pubic turn, with the instruments. Many years ago, when I was inexperienced, I put a woman across the bed on her knees and elbows, slipped my fingers up the rectum over the occiput, and pulled the occiput down, thus flexing the head; the head, thus well flexed, was born immediately.

## RAPID DELIVERY IN PLACENTA PRAEVIA.

DR. CHARLES J. HILL AITKEN (Kilnurlust, Rotherham) writes: After the second haemorrhage in a marginal placenta praevia in a primipara the membranes were ruptured. The os was only opening and the child was large, so turning was considered inadvisable. There was no further haemorrhage. A day later labour had not set in and the patient was febrile. Although knowing the danger of rapid delivery in placenta praevia (BRITISH MEDICAL JOURNAL, October 2nd, p. 585), the risk was considered less than what might happen if we waited. Pituitrin 1 c.cm. was injected, and within ninety minutes the child was born. There was no bleeding during the third stage, so presumably there had been no tear of the rapidly dilated cervix. There was no post-partum haemorrhage.

## "NIGHTCAPS" FOR THE AGED.

DR. T. D. HARRIES (Aberystwyth) writes: Now that we are in the grip of winter a few remarks concerning "nightcaps" might be of interest to those who have to administer to the care and comfort of the aged. There are many kinds of nightcaps worthy of consideration. The old man's nightcap is usually understood to be a covering for the head during cold winter nights, and so well known is the comfort it affords by the way of procuring sleep that its use is almost universal amongst those who dwell amid the Welsh mountains. The caps are of knitted wool, at which the Welsh women are adepts. Another class of "nightcap" is for internal administration, in which a variety of potions are included, some being of great antiquity, such as "rum punch" which is too well known to require comment, beyond that it is of an agreeable nature and produces a feeling of comfort sufficient to ensure a comfortable night's rest. Other useful "nightcaps" are bovril or milk at blood heat; the milk might under certain conditions be usefully reinforced by the addition of a well whipped egg and a tablespoonful of brandy or rum, which renders it more digestible and palatable. There is another time-honoured "nightcap," familiar to those who can recall the old coaching days, when, on arrival at certain stages, spiced ale, better known as "purl" in those days, was kept in readiness to restore the vitality of the shrivelled-up passengers, who were suffering from cold feet, benumbed hands, cold ears, pinched noses, glued lips, and silent tongues. The transformation following a deep quaff of the elixir was beyond description—a glow of warmth was experienced, proclaimed by a natural flush of the face and restored waggle of tongues, the feeling of comfort and joy, brought forth good-natured liveliness, which continued until the happy passengers were in the arms of Morpheus. Some of the "nightcaps" referred to have for ages passed the experimental stage, and have proved their worth in providing mental and bodily comfort during the closing stages of life, and should not be abandoned to make room for the deadly dopes which have become so fashionable of late years. Of all "nightcaps" the one I advocate for the use of old people who are denied peaceful sleep from lack of vitality is "spiced ale," which is made of strong ale brought to the boil, to which is added sugar, butter, ginger, and nutmeg. As to the therapeutic properties of this cordial, we need not trouble as long as we know that it acts as a harmless prop to the old and decrepit who have gone beyond the age of being revitalized by "vitamin" or rejuvenated by "monkey gland."

## FRENCH MEDICAL PROPAGANDA IN THE FAR EAST.

THE General Secretary of the Académie de Médecine of Paris, Professor Charles Achard, recently went on a mission to Japan for the purposes of studying methods for bringing about more intimate intellectual relationships between that country and France. Incidentally he visited also Southern China and Indo-China, and in the course of his journey called upon French professors in the universities of Quebec and Montreal. In a communication to the Académie, Dr. Achard reported that while Japanese doctors are acquainted with English and German medical literature, publish their works in English or German, and even receive visits from German professors, French publications are few, and French medicine consequently little known. There is, however, a Franco-Japanese House in Tokyo, which could be used as liaison agent between the two countries, and could distribute medical publications amongst the libraries. It is hoped to organize visits of Japanese doctors to France, and to send delegates to congresses in Japan. Dr. Achard attended various discussions, and addressed a congress in Tokyo on anti-

typhoid vaccination. He concludes his communication to the Académie by stating that the field for French medical propaganda in the extreme East is very large. In Japan, where medicine hardly differs from European medicine, except in method, interpretation, or expression, French propaganda should consist in making better known the scientific publications, the welfare efforts, and the social medicine of France. In China, on the other hand, European medicine is little practised; and France ought to assist in organizing scientific medicine in that country, especially, perhaps, at Canton. Indo-China is French, so that propaganda is hardly needed. But every effort should be made to impress French influence on the population. Native doctors must be trained; medical teaching developed; welfare schemes multiplied; and scientific research endowed. Every nation, says Dr. Achard, which wishes to exercise influence in the world, in the intellectual domain no less than in that of material interests, must without ceasing display its flag. In the Far East France must make the necessary effort, no less than her rivals, to unfurl the national colours.

## THE TOOTH-BRUSH: BOON OR BANE?

DR. J. M. writes: Now that the tooth-brush has become one generation the question might be asked—good or harm? On visiting the average house I see lying somewhere about the bathroom a tooth-brush of any age from three to six months, which probably has never been sterilized, and which smells accordingly. Teeth and gums may be infected already, but what of the infection that is forced into the gums with this ragged instrument, which scarifies before it infects? Attention has been directed recently to the finding of septic germs about the teeth and gums, but what of the dead matter and the resulting sapraemia which, after prolonged action, paves the way for septicæmia? Can the ordinary tooth-brush remove the particles from between the teeth, or does it give but an appearance of superficial cleanliness? Some dentists believe that a rubber tooth-brush with vulcanite handle, which can be readily sterilized by boiling, is more efficient and does less injury to the gums. Is the tooth-brush efficient, or should some other means be encouraged to remove dead and decaying matter from between and behind the teeth?

## AN ENTERTAINING TRADE JOURNAL.

THE indefatigable Dr. Cabanès, whose books on curiosities in medicine we have noticed from time to time, has just published a new volume entitled *La Chronique Médicale*, which is a review of historical, literary, and magazine appears to be financed by a firm of manufacturing chemists, but, modestly, they do not occupy more than a page of letterpress and all the advertisement space with descriptions of their wares, leaving the rest to Dr. Cabanès. An article in a recent issue was written by a collector named Froehner, who died in 1925, and is entitled "Anthropology of Greek vases." He sought to show how all the words used by the Greeks in describing different parts of vases, bottles, and other vessels had reference to various portions of the human body. The fiftieth anniversary of the death of George Sand leads Dr. Cabanès to a series of thoughts and impressions which he calls "Sandiana." George Sand at one time was accustomed to dress in male attire, for purposes of economy it is said. Dr. Cabanès reproduces a caricature of the period, and a glance at the authoress in a *redingote-guêrite* makes it easy to agree with the writer who said there was nothing very seductive in her appearance. *La Chronique Médicale* indulges also in ghost stories, and a number of miscellaneous notes, such as that, on account of his vivacity, the Prince de Ligne was forgiven the lice with which his armchair was be-starred!

## THE PREPARATION OF ANTIVENIN SERUM.

A GRAPHIC account of the process of collecting the venom of rattlesnakes at the San Antonio station of the Antivenin Institute of America is contributed by Colonel Martin L. Grimmins to the *Journal of the American Medical Association* for November 13th. The rattlesnakes are snared with a leather loop at the end of a whipstock, or the snake is pinned to the ground by a forked stick. The snake is then grasped behind the head, which is held over a Petri dish; with the right thumb and forefinger the venom glands are pressed, causing the venom to be ejected through the fangs into the dish. The venom, which dries rapidly, is pipetted off about every ten minutes and centrifugalized, when four layers can be distinguished, the top being amber, the second opalescent, the third colourless saliva, and the fourth cells. The upper two layers are dried in an incubator at 37° C. for from two to four days, when crystals appear. Two hundred Texas diamond-back rattlesnakes (*Crotalus atrox*) produce about 2 oz. of liquid venom, which yields 1 oz. when crystallized. The venom is sent to the Mulford Biological Laboratories, where twenty horses are immunized in a similar way to that employed in the case of diphtheria and tetanus.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 44, 45, 48, 49, and 50 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at page 46.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 256.

## Remarks.

ON

## THE CAUSATION OF THE INCREASED INTRACRANIAL PRESSURE ASSOCIATED WITH TUMOURS WITHIN THE CRANIUM.

(Preliminary Note.)

BY

JOHN S. B. STOPFORD, M.D.,

PROFESSOR OF ANATOMY AND DEAN OF THE MEDICAL SCHOOL,  
UNIVERSITY OF MANCHESTER.

Many theories have from time to time been suggested to explain the etiology of the increased intracranial pressure which is so frequently associated with tumours within the skull. Nevertheless the matter is still largely shrouded in mystery, although careful observations made upon large series of cases by a number of investigators offer some significant information. Although clinical evidence of raised intracranial pressure as manifested by headache, vomiting, and choked disc is not an absolutely constant accompaniment of tumours within the cranium, it is generally agreed that it occurs at some time in the course of the disease in upwards of 80 per cent. From researches which have been made with regard to the presence or absence of increased intracranial pressure it is clear that the anatomical site of the tumour is of first importance. The rate of growth and size of the tumour also have some influence, but they appear to be of much less significance than the anatomical situation. The histological character of the growth apparently bears no relation to the occurrence or absence of increased intracranial pressure.

Since the site of the tumour is the factor of fundamental importance, it would seem that the causation of the increased pressure might probably be of mechanical origin. The influence of rate of growth and size of the tumour is also compatible with a mechanical origin, since a slow-growing or small tumour would often permit some compensation for the mechanical disturbance, which is less possible in the case of growths rapidly increasing in size. When we examine the situation of tumours which are most frequently associated with manifestations of raised intracranial pressure further light is shed upon the problem. It is well known that tumours of the mid-brain and subtentorial growths practically always cause intracranial tension, whereas tumours of the pons do not as a rule, unless they invade neighbouring regions. Furthermore, on studying records of patients it is found that signs of increased tension are frequently absent in the case of growths of the frontal region, and less frequently absent in the parietal and occipital regions. The constancy of the occurrence of increased intracranial tension with subtentorial growths might at first sight suggest pressure upon the lateral sinuses, leading to interference with the absorption of cerebro-spinal fluid and its accumulation, with resultant rise of pressure within the skull; further reflection, however, makes such a contention untenable, and it is quite unnecessary in this paper to discuss the overwhelming evidence against such a theory.

Reflecting upon the information cited with reference to the situation of the tumour, compression of the great vein of Galen appears, on anatomical and physiological grounds, to be a much more likely cause for the increased pressure.

With this in mind I recently re-investigated the exact course and relations of this vein, and found them strikingly different from those figured in most anatomical textbooks. By the usual anatomical approach the falx cerebri and the tentorium are disturbed before the vein is examined, and its precise relations and direction are consequently grossly modified. Removing a segment of the calvarium by means of a horizontal saw-cut above the level of the tentorium and a sagittal one about half an inch lateral to the superior longitudinal sinus, it is possible to dissect away the cerebral hemisphere and display the origin, full course, and termination of the great vein of Galen as it really exists with the parts in its immediate vicinity intact. Such a dissection is shown in the accompanying drawing, and it will be seen that the vein passes at first backwards and upwards, and then forwards and upwards, to reach the hinder end of the inferior longitudinal sinus, curving round and in contact with the splenium of the corpus callosum. The relation with the splenium is always found to be most intimate, and the vein opens into the sinus as the meningeal tributaries open into the superior longitudinal sinus—that is to say, against the flow of the current in the sinus. Taking this course, which is much more vertical than horizontal, it will at once be noticed that anything which elevates the

tentorium is certain to exert tension upon the vein and cause it to be compressed against the splenium. Lateral deflection of the falx cerebri, owing to its attachment to the tentorium, will similarly raise the tentorium and cause the same effect, although not so readily as direct elevation of the tentorium from below. The more rapidly the tension on the vein is applied, the greater must be the risk of compression.

Generally speaking, subtentorial growths and tumours in the parietal and occipital parts of the cerebral hemisphere are obviously more likely to produce this tension, and the suggested consequent compression of the vein, than those occurring in

DRAWING of dissection described in text, to show the relation of the great vein of Galen to the splenium. Part of the inferior longitudinal and straight sinuses have been incised to display the termination of the vein. S.—splenium.

the frontal region, which will only deflect the narrower apical part of the falx cerebri. Reference to the position and form of the falx cerebri and its attachment to the tentorium will show that very considerable lateral deflection would be required in the frontal region, and much less in the parietal and occipital regions, to produce elevation of the tentorium. Mid-brain tumours must be so near to the vein at its origin that direct pressure upon it, or compression of it against the splenium, is exceedingly probable in practically all cases. Tumours of the pons, on the other hand, are not likely to cause any interference with the vein for anatomical reasons, unless they invade neighbouring regions.

The question still remains to be answered as to how compression of the great vein of Galen can cause increased intracranial pressure. Compression of this vein near its origin will produce obstruction to the venous drainage from the choroid plexuses of the lateral and third ventricles, since the veins from these plexuses are tributaries of the two veins of Galen which lie in the volum interpositum and fuse to form the great vein of Galen. Such obstruction must produce an increased capillary pressure in the choroid plexuses, which is likely to lead to an increased production of cerebro-spinal fluid. Fortunately there is convincing experimental evidence to prove the latter statement. Dandy<sup>1</sup> has recently proved that occlusion of the great vein of Galen in dogs, provided it occurs at the origin of the vein and the development of a collateral circulation is thus

prevented, causes internal hydrocephalus on account of the overproduction of cerebro-spinal fluid. As would be anticipated, Dandy found that the hydrocephalus developed more slowly than if caused by occlusion of the aqueduct of Sylvius. In addition to this experimental evidence, a few cases have been reported of internal hydrocephalus, caused by thrombosis of the great vein of Galen or pressure upon the straight sinus. These suggestions may be criticized, owing to the fact that obvious internal hydrocephalus is not an invariable or essential accompaniment of increased intracranial pressure from tumour. With reference to this it must be remembered that in Dandy's experiments, and in most of the reported cases, the venous obstruction was complete, and the cerebro-spinal fluid was produced in such large quantities that internal hydrocephalus was induced. Less complete obstruction is likely to cause less overproduction of fluid, and slight or negligible dilatation of the ventricular system, but sufficient to produce an increased intracranial pressure.

## SUMMARY.

1. It is shown that the great vein of Galen is situated in such a position that it may be compressed against the

splenium of the corpus callosum indirectly or directly by tumours occupying sites which are known to give rise most constantly to increased intracranial pressure.

2. Such compression is not so likely in the case of tumours occupying situations which are known to cause less frequently increased intracranial pressure.

3. Experimental and clinical evidence has been submitted by Dandy and others that occlusion of the great vein of Galen leads to internal hydrocephalus from overproduction of cerebro-spinal fluid.

4. It is suggested that moderate compression without complete occlusion of the vein is likely to give rise to increased intracranial pressure, accompanied by slight or negligible dilatation of the ventricles.

5. If the views put forward in this paper are correct, the increased pressure caused by intracranial tumours is due to an excessive production of cerebro-spinal fluid, the fluid being produced in such quantities that absorption cannot keep pace with production, and the intracranial pressure being consequently raised.

E. MUIRHEAD LITTLE, F.R.C.S., in the Chair.

## DISCUSSION ON SPASTIC PARALYSIS.

## OPENING PAPERS.

I.—WILLIAM J. ADIE, M.D., F.R.C.P.,

Physician to Out-patients, National Hospital, Queen Square, London.

I ASSUME that the organizers of this discussion, when they chose the title of "spastic paralysis," intended that we should accept the word "spastic" in a strict sense and confine our attention to conditions in which stiffness and weakness of the muscles result from disease of the pyramidal system. Rigidity, paralysis, contractures, and deformities from extrapyramidal motor disease and from disease of the lower motor neurone or of the bones and joints, therefore, are outside the limits of our subject.

Further, we are concerned in this Section with spastic paralysis in children; hence the inflammations, degenerations, and compressions that account for most of the cases of spastic paralysis in adults, though many of them occur in children, may well be excluded from the medical part of our discussion, so that we may devote our time to some special morbid processes that produce their effects before or during birth or in early life—the cerebral diplegias, infantile hemiplegias, diffuse cerebral sclerosis, and certain familial diseases.

The commonest and therefore the most important of these is the form of cerebral diplegia generally known as Little's disease. Strictly speaking, Little's disease is a spastic diplegia associated with abnormal birth, characterized by a preponderance of rigidity over paralysis, the legs being most affected, and a tendency to recovery, but it is customary now to apply the name to all cases, whether birth is normal or abnormal.

To the accurate clinical description given by Little, an orthopaedic surgeon, more than eighty years ago, nothing material has been added, but controversy still rages concerning the pathogenesis of his disease. According to many, injury to the brain at birth is the most important etiological factor; according to some, the cause, whatever it is, acts during intrauterine life. In his presidential address delivered before the Neurological Section of the

Royal Society of Medicine Dr. James Collier gave a memorable exposition of his personal views on the pathogenesis of cerebral diplegia, and set forth the following conclusions: hereditary and familial influences are extremely rare; maternal ill health during pregnancy has been placed in an important position by many writers, but without justification; abnormalities of birth are common but by no means constant associates of diplegia, and they may be excluded as causal factors; the essential anatomical lesion is a primary degeneration of cerebral neurones from causes at present unknown; the evidence demands the verdict that meningeal haemorrhage should be deleted as a causal factor of any infantile spastic state.

Dr. Collier has shepherded or cudgelled most of us into what he considers to be the way of truth in this matter, but the last word has not been said and the subject is still open for discussion. Those who oppose his view are likely to marshal an array of facts which are not easily set aside; they would strengthen their position materially if they took their stand upon "birth injury," rather than the more particular "meningeal haemorrhage," as the most important etiological factor.

It has been said that such dissimilar factors as premature precipitate birth and prolonged and difficult labour could not produce the same effects. But cerebral lesions are most frequent proportionately in premature infants, while it cannot be denied that injury is likely to occur readily during a protracted labour. It is said, too, with truth, that in many cases of diplegia the labour was normal in every respect. But the brain may have been injured nevertheless, for one of the most important factors in producing birth injuries is one to which little consideration has been given in discussions on this subject, for the good reason that its existence was unknown. I refer to the mechanism described by Schwartz, who has shown that injury frequently occurs in the brain under the presenting part of the head, due to differences in intrauterine and atmospheric pressures.

This factor may be very important when labour is normal in its time of onset and in its duration. The remarkable researches upon the mechanism of birth injuries and the pathological changes produced thereby that are being carried out in Frankfurt by Schwartz and his associates demand the careful attention of obstetricians, paediatricians, and neurologists alike. Many hundreds of brains from children who have died during the first seven months of life have already been examined; in 65 per cent. of them pathological changes due to birth injury were visible to the naked eye; by comparing the appearances in brains from children who lived a few days only with those who died after weeks, months, or years, it has been possible to follow the changes that occur in and around birth injuries and to recognize them at all ages.

Perhaps the most important part of Schwartz's work is

the new light it throws on the mechanism of birth injuries, his demonstration of their great frequency, and of the decisive part they play in producing much of infantile mortality that is at present attributed to other causes. The part that is pertinent to our present subject is that which deals with the appearances in children who have survived some years.

In many of these the lesions are gross; in most they are confined to the white matter; but in some they are cortical, and in a few they are indistinguishable from the atrophic and lobular scleroses that have been found in many cases of cerebral diplegia. Significance has been given to the fact that in some cases of diplegia there is no gross lesion, only a fine microscopical change; any gross change that may be present in other cases—atrophic scleroses and the like—is held to be a natural consequence of the primary neuronie degeneration. However this may be, it is certain that diplegia without a gross macroscopical change in the appearance of the brain is extremely rare, and Schwartz's work seems to prove that atrophic scleroses may result from injury to the brain sustained at birth.

In thinking over this subject I asked myself if injury to the brain during life ever produces effects comparable with Little's disease, and I recalled the remarkable clinical picture presented by men who had sustained a gunshot wound of the vertex with injury to the superior longitudinal sinus, a condition of which I saw many examples during the great war.

Three men lay with legs extended, the arms flexed and adducted; the degree of rigidity in the limbs was astonishing; it affected the legs most, diminished upwards, and left the hands free. The upper parts of the motor cortex suffered most because their veins drain into the superior longitudinal sinus; lower parts suffered less because they are drained through other channels. In adults this rigidity passes off rapidly; but it is conceivable that vascular disturbances over the vertex of the kind that Schwartz has described in infants may produce more lasting damage to their young and more vulnerable cortical cells.

I do not wish to stress the point unduly, but for the purpose of promoting discussion I mention the facts—first, that the brain is often injured during birth beneath the presenting part; and secondly, that certain vertical lesions in adults produce a transitory clinical picture of Little's disease in its purest form.

There are two features of ordinary diplegia that I find hard to reconcile with the notion of primary neuronie degeneration as the essential anatomical cause. One is that the disease is hardly ever familial; the other is that in practically all the conditions in which primary neuronie degeneration is generally accepted as the anatomical cause the course of the disease is progressive to death, or up to a point peculiar to the disease or to the affected family, whereas a tendency to improve is highly characteristic of ordinary non-familial diplegia.

Familial cases, indistinguishable clinically from the common isolated cases, have been recorded, but I am impressed rather by their great comparative rarity than by their actual occurrence. In the familial cases, I suspect, pathological examination would reveal changes very different from those usually found in the common non-familial form. In spite of rare exceptions the rule holds that non-familial diplegia from birth tends to improve, whereas post-natal and especially familial diplegia tends to progress.

Whatever the significance of this may be with regard to pathogenesis the distinction is a very important one in practice, and it causes me to express the opinion that non-familial diplegia from birth is entirely distinct from the various forms of non-familial post-natal diplegia. My own feeling is that Little's disease is a clinical syndrome, and that the etiology differs in different cases.

After all, it matters little for practical purposes whether the damage is pre- or intra-natal; the important fact is that diplegia from birth, whatever its cause, tends to improve; in these cases much can be done by appropriate surgical treatment, but the cases must be carefully chosen. Gross mental defect is a contraindication, but where this is moderate, operation, by enabling the child to move about

and get into touch with its surroundings, animate and inanimate, may bring about an improvement in the mental state.

I find that there is a tendency to overestimate the severity of the mental impairment in diplegic children. A grotesque appearance and speech which is so dysarthric as to be unintelligible to a stranger may be present in a highly intelligent child. I see a girl from time to time who at first sight would be taken for a hopeless idiot, but she is highly educated, an omnivorous reader, and a leading light in the local Girl Guides. In any competition from which her physical disabilities do not preclude her she is a regular and easy winner.

I remember well a friend of my childhood who was diplegic; his speech was so defective that he was nicknamed Dutchy, but he was the brains of any company in which he found himself, and took the lead naturally in all our games and escapades. I have observed remarkable and, to me, quite unexpected improvement in the mental condition of many of these children, and I should not be inclined to look upon mental defect as a bar to operation unless this were obviously very gross.

Diplegia and epilepsy is an unfavourable combination; my impression is that fits which are symptomatic of organic brain disease are more difficult to control than idiopathic epilepsy; if the fits are not easily controlled by appropriate remedies the surgeon should hesitate before operating on the limbs, as the prognosis for the mental condition is bad. We see epilepsy more frequently as a complication of post-natal infantile hemiplegia—for example, after poliomyelitis—than with diplegia from birth; here again it is not an absolute bar to operation if the fits are infrequent or controllable.

Operation is hardly worth while when involuntary movements are a prominent symptom. Athetoid and choreiform movements at rest are most often seen in hemiplegias and double hemiplegias, whereas in diplegia from birth, if they are present at all, they are more likely to occur on voluntary movement only, but the distinction is not absolute.

Of the familial diplegias amaurotic family idiocy merits special mention, as our knowledge of this disease is increasing rapidly. The classical form is that first recognized from its ocular changes by Waren Tay in 1881, and more fully described later by Sachs. It appears in infants during the first year of life, chiefly, but not entirely, in the Hebrew race, and is characterized by progressive mental impairment, progressive spastic paralysis, and progressive loss of vision, with a cherry-red spot at the macula; it usually ends in death before the age of 2 years. For a time it was thought that the disease existed in this form alone, for the same symptoms, the same course, and histological changes identical with those described by Kingdon and Russell, and eight years later by Schaffer, characterized all the published cases.

In 1903, however, Batten described some cases that differed from the Tay-Sachs form in their later onset, slower course, non-racial incidence, and different ophthalmoscopic appearances. This form is known as the Batten-Mayou type and as the infantile form of Spielmeyer and Vogt. Later still Jansky and Bielschowsky described the late infantile form that begins in the third or fourth year. Finally, a number of cases have been observed at ages beyond childhood—the late forms.

For descriptive purposes it is perhaps expedient to retain the names of these forms, so long as we remember that there is nothing distinctive about them and that transitions occur from one to the other. The infantile Tay-Sachs form is fairly constant in its manifestations, but the post-infantile forms show great variations in their course and symptomatology, although the classical triad—blindness, paralysis, and dementia—characterizes them all. The post-infantile forms are seen most often in Gentiles.

The cherry-red spot at the macula is confined to the infantile form and is present in almost every case. In the post-infantile form the characteristic ophthalmoscopic change is a disturbance of retinal pigment, a kind of retinitis pigmentosa, in the macular region. It is by no means constant, however; in some cases it is associated with pallor of the disc, in others this alone is present, in others vision is unaffected and the fundi are normal. Defective

vision with normal fundi and pupillary reactions has been observed: in these cases the lesion causing the visual disturbances must be in the optic radiations or in the occipital lobe.

In one member of a family illustrating the juvenile form that I showed last year before the Children's Section of the Royal Society of Medicine characteristic disturbances of the retinal pigment were detected more than a year before other symptoms appeared; I was thus able to foretell that this unfortunate boy would ultimately succumb to the disease as his elder brothers had done.

The age of onset varies in different families but is remarkably constant in each. In the late infantile form it is usually between the third and fourth years; in the juvenile form it is usually between the sixth and tenth years; in the late forms it has occurred as late as the twenty-sixth year. As a rule the course is shorter the earlier the onset; most infants with the Tay-Sachs form die before the second year of life is completed; in the late infantile cases the duration is usually about three or four years, in the juvenile cases it is usually several years longer, but remarkable exceptions occur. One patient who had been mentally defective from the age of 2 years died in his twenty-third year; another, normal till the age of 10, also died at 23; another child began to fail mentally at the age of 10, had fits from the age of 13, and survived till 26; another, whose symptoms appeared in his twelfth year, died aged 21. Finally, a young woman who had been normal in every respect until her twenty-sixth year lived till she was 38. The diagnosis in all these cases was confirmed by microscopic examination of the brain. The brother of the last mentioned patient showed his first symptoms at the age of 10 years, and was still alive at the age of 38.

Another generalization I should like to make is this: the younger the onset, the more likely it is that all the children in the family will succumb to the disease. I have seen a healthy young Jewish adult three of whose younger brothers died of amaurotic family idiocy, so my rule is not absolute, but it is very nearly true.

The chance of some of the children escaping improves slightly in the late infantile and juvenile forms; in the late forms, where the onset is at 10 or 12, or later, and life is prolonged into the twenties and thirties, most members of the family are normal, and in some instances only one child is affected.

I should like to record here my conviction that *ad hoc* examinations of earlier generations of amaurotic families will reveal evidence of a degenerative tendency in the stock with a frequency that is at present not suspected. Holmes and Greenfield state without comment that an uncle of one of their patients was mentally defective and unable to read; in another family an aunt was blind and demented; in another the father and an aunt, though normal in other respects, had defective vision, which was found to be due to retinitis pigmentosa. It happened that the affected children in this family had normal vision and normal fundi. I suggest that, just as in another heredo-familial disease—dystrophia myotonica—cataract occurs in the otherwise healthy parents and more remote ancestors of children who present the muscular and other manifestations of the disease but may or may not have cataract, so pigmentary degeneration of the retina may be found in the otherwise healthy ancestors of children with amaurotic idiocy who may or may not present retinal signs.

In addition, then, to the cases of amaurotic idiocy with classical symptoms and a uniform course there are many that present atypical features. The cardinal symptom, blindness, may be absent; the fundi may be normal; sometimes no evidence of familial incidence can be obtained; feeble-mindedness far short of idiocy may be the only clinical manifestation of the disease; far from being steadily progressive it may remain stationary for decades. Nothing is constant except the pathognomonic change in the brain.

It is my practice to consider the possibility of amaurotic idiocy being the cause in every case of idiocy, feeble-mindedness, epilepsy, or diplegia, and I look upon an inquiry for visual troubles in the parents and other relations; and an ophthalmoscopic examination of them when

possible, as a part of the routine investigation of such cases. I need hardly say that the disc and the macular region must be examined carefully in all children with these diseases.

I suppose we shall retain the name "amaurotic family idiocy" for this disease, but you will agree that it is hardly suitable for cases without blindness, familial incidence, or idiocy. "Progressive cerebro-macular degeneration" is no better, for the macula may be healthy and the disease may remain stationary for many years.

In a special class among the diplegias, with spastic paralysis as a cardinal symptom, I place together the familial forms to which the name of the writer who first described them is usually attached. I shall not attempt to name them all; the clinical features—increasing spastic paralysis, mental deterioration, and sometimes blindness—are common to each form, but the pathological changes vary.

The Merzbacher-Pelizaenus "disease," of which much has been written, has been found in members of one family only, but Merzbacher thinks that some of the earlier cases of diffuse sclerosis described by others were examples of his disease. Krabbe found almost identical changes in two unrelated families and in one apparently isolated case; Scholtz found very much the same changes in another family. Otherwise, although the changes are the same in different members of the same family, each family constitutes a so-called form or type in itself. The onset in these familial cases is almost always definitely post-natal, and the course is almost without exception steadily progressive to death.

In a third class I place the heredo-familial spastic spinal paralyses and the closely related ataxic and non-ataxic forms of Friedreich's disease. Their features are well known and I have nothing new to say about them.

Finally, progressive spastic paralysis, mental deterioration, and sometimes blindness, characterize non-familial cases that are included under the comprehensive title of diffuse sclerosis. It is not yet possible to give a classification of the different pathological conditions that comprise this group, but its limits are being gradually narrowed as one form after another is withdrawn from it.

I have mentioned the familial forms of diffuse sclerosis connected with the names of Krabbe, Merzbacher-Pelizaenus, and Scholtz—there are many others; of the non-familial forms the one that deserves special mention is that described by Schilder in 1912 as encephalitis periaxialis diffusa. Some thirty cases of this disease have been published. You may think that a disease of which so few cases have been published is very rare and hardly worth mentioning; on the contrary, the fact that thirty cases have been recorded since 1912 indicates that it is not very rare, and that it is one which those of us who see many unusual cases will certainly encounter in the course of our routine work.

In less than two years I have seen seven most obvious examples of a certain disease; about forty cases have been published abroad; so far it has not been adequately described in English, but it must be very common. We only recognize the things we know.

On considering all the published cases of Schilder's disease I thought at first that it would be impossible for me to give a useful account of it in a few words, as the age at onset, duration, and symptoms varied greatly in different cases, but on analysing the symptoms in children of 14 years and under I find that between these ages its manifestations are fairly constant.

Somewhat less than half of the cases occurred in children under 14. One child was aged 1 year; in the remainder the average age at onset was just under 8 years. In the child aged 1 year and in another aged 12 the duration of the disease is given as a few days only; in the others it varied from two months to two and a half years, with an average duration of just over one year. In the infantile cases males outnumbered females by three to one. The disease is not familial. In Schilder's second case (called by some Faberfeld and Spieler's case) another child of the same parents is said to have died at the age of 8 years of a similar malady; but this child was not seen by

a competent physician, its brain was not examined after death, and the nature of its symptoms is doubtful.

The first obtusive symptom may be difficulty in walking, mental deterioration, failing vision, or epileptiform attacks. The most constant symptoms are spastic paralysis and mental deterioration; then, in order of frequency, speech defects, defects of vision, tonic and clonic spasms, and various signs of increased intracranial pressure.

The mental disturbance begins as apathy and passes on to complete mindlessness; dysarthria, aphasia, or mutism may be early symptoms. Failing vision was noted in less than half of the infantile cases; usually it is associated with papilloedema and defective pupillary reactions, but in several cases, although vision was grossly defective, the fundi were normal and the pupillary reactions were brisk. This, as Dr. Collier has said, is the sign manual of occipital disease. It occurs when the morbid process begins in the occipital region. It was the combination of occipital blindness with spastic paralysis and progressive dementia that enabled Dr. Collier to recognize the first case of Schilder's disease that was diagnosed during life. The same combination with normal fundi has been seen in amaurotic family idiocy, but it is almost pathognomonic of Schilder's disease, and if its incidence is non-familial this diagnosis can be made with considerable confidence.

Fits indistinguishable from idiopathic epilepsy occurred early in some of the cases, and convulsions or spasms of some sort were observed during the illness in about half the cases. In three cases headache and vomiting aroused the suspicion of cerebral tumour.

I do not doubt that as the number of carefully observed cases of this form of diffuse cerebral disease increases, as it is sure to do rapidly, we shall learn to detect Schilder's disease more readily than is possible at present.

The compressions, degenerations, and inflammations that account for most of the cases of spastic paralysis in adults almost all occur in children, but time does not permit me to name them or to refer to their peculiar clinical features.

In some cases of spastic paralysis there is a natural tendency to improvement which may be hastened or increased by operative measures, in some the disease will certainly prove fatal unless cured by surgical measures; in others the outlook is hopeless and surgical treatment is worse than useless.

Sometimes, I fear, unnecessary or unsuitable operations are performed; perhaps these brief remarks on some of the numerous and entirely dissimilar diseases of which spastic paralysis may be a sign will serve to show that close collaboration is necessary between neurologist and surgeon before operative treatment is undertaken for the relief of spastic states.

Finally, with regard to the neurological problems presented by spastic paralysis: recent studies on decerebrate rigidity have added greatly to our knowledge of the physiology of muscle tone, but so far they have given no clear indication for new methods of treatment. Nevertheless the clinician takes a lively interest in experimental work on decerebrate rigidity because, as Dr. Walsho has taught us, the disturbance of tone and the reflex phenomena of spastic paralysis in man are identical with the tonic and phasic reactions described by Sherrington in decerebrate animals.

It is common knowledge that decerebrate rigidity occurs in animals when the brain stem is completely divided at any point between the lower part of the medulla and the upper part of the mid-brain. Transection immediately cephalad to the mid-brain produces little alteration in tone, but if sections are then made more and more caudally, a point is reached when decerebrate rigidity suddenly appears. This has been attributed to damage of various structures by different investigators, but Rademaker has proved conclusively by a series of beautiful experiments that rigidity is absent so long as the red nucleus is intact.

Lesions interfering with other structures at the same level never produce decerebrate rigidity, but one confined to the red nucleus or its efferent fibres in the decussation of Forel produces it constantly. This rigidity is not removed by ablation of the cerebellum, and it occurs in a decerebrate animal from which both labyrinths have been removed (Magnus). It disappears completely when a

section is made across the medulla at the level of the calamus scriptorius just caudal to the point of entry of the eighth nerve. It is not yet known which structure in the medulla is responsible for the rigidity. Deiters's nucleus and the olive have been named; perhaps some day we shall see bold surgeons removing the olives for the relief of spasticity.

A comparison of the results obtained by dividing the efferent fibres of the red nucleus in decerebrate animals and in animals with an intact cerebrum suggests that the pyramidal tracts act with the red nucleus to antagonize the medullary centres. In the decerebrate animal, where the pyramidal tracts are already divided, section of Forel's decussation causes extreme rigidity; in an animal with intact pyramidal tracts this lesion produces rigidity, but it is much less intense.

There is one difference between the results of experiments on animals and the results of disease in man which causes difficulty when one attempts to correlate them. In animals whose brain stem has been divided just in front of the mid-brain—that is, in an animal devoid of its thalamus and with both pyramidal tracts divided—the amount and distribution of muscle tone is normal. In man many disorders of muscle tone appear to result from damage to the pyramidal tracts and the basal ganglia; perhaps some of those who take part in this discussion will develop this aspect of a highly complicated subject.

In conclusion I shall merely mention the alleged sympathetic innervation of striated muscle. It may well be that sympathetic nerve fibres reach striped muscle fibres and exert an important trophic influence upon them, but the evidence available at present does not support the notion that the sympathetic plays any part in the regulation of muscle tone.

Gaskell showed long ago that the sympathetic nervous system is not a separate nervous system interchanging fibres with the cerebro-spinal system, but is formed by fibres given off from the cord; Langley made it clear that the autonomic system, of which the sympathetic is a part, though capable to a certain degree of independent action, functions under the control of higher centres. These higher centres, from which, as I believe, all impulses pass that reach the sympathetic, are situated at a level cephalad to the point of election for the section producing decerebrate rigidity; if my assumption is correct, sympathetic impulses to the muscles, if these exist, are cut off by the very section that produces decerebrate rigidity. However this may be, it is certain that complete ablation of the sympathetic system has no effect on decerebrate rigidity, hence division of sympathetic fibres is not likely to influence spasticity. Perhaps surgeons who have performed sympathetomy in spastic states will communicate their results during the discussion.

## II.—A. S. BLUNDELL BANKART, M.Ch., F.R.C.S.,

Consulting Surgeon, Queen's Hospital for Children;  
Orthopaedic Surgeon, Middlesex Hospital.

SPASTIC paralysis is not a disease, but a physiological state—the natural physiological result of the anatomical condition present in any given case. It closely resembles, if it is not identical with, the condition known as decerebrate rigidity, which is produced experimentally by section of the brain above the level of the mid-brain. The result of such a lesion is to remove the inhibitory and controlling influence of the cerebral cortex from the parts of the central nervous system below, which parts then enter into a state of abnormal reflex activity.

Chief of these effects is an exaggeration of the postural reflex which normally maintains the upright position of the body, and whose centres are situated in the mid-brain. This is essentially a continuous act of extension of the lower limbs and spine. Secondly, there is loss of the influence of the upper motor neurone which normally correlates the actions of different muscle groups in the performance of voluntary movements. In other words, there is paralysis of reciprocal innervation, so that the muscles on one side of a joint do not relax when those on the opposite side contract. Thirdly, there is loss or impairment of the power of voluntary movement.

This condition is due in the great majority of cases to a permanent defect of the upper motor neurone. It is therefore essentially an incurable condition, and the most that can be expected from surgical treatment is relief from some of its most obvious mechanical or functional disabilities. Briefly, it may be said that anything which interrupts the cortico-spinal or pyramidal tract in any part of its course will give rise to spastic paralysis corresponding in extent and distribution to the part of the tract that is destroyed. The manifold conditions which may cause such a lesion concern the orthopaedic surgeon only in so far as they determine the extent and distribution of the paralysis, its progress, if any, and the complications which may accompany it.

The pyramidal tract may be involved in a congenital defect of development of the brain or spinal cord; it may be injured by direct violence or by haemorrhage, either on the surface of the brain (meningeal haemorrhage of infants) or in the substance of the brain (cerebral haemorrhage of adults), or it may be damaged by inflammatory processes (encephalitis, polio-encephalitis, myelitis) either before or after birth.

The cases with which we have to deal are chiefly, though not exclusively, the cerebral palsies of children—diplegias, hemiplegias, paraplegias, and, less often, monoplegias. By the time such cases come for surgical treatment the primary lesion is almost invariably permanent and stationary, and the spasticity is the terminal physiological state.

Cases of progressive paralysis, both syphilitic and non-syphilitic, occur, but I think they are recognizable by ordinary clinical methods, so that they do not often come for surgical treatment. I confess to having performed routine operations on cases of spastic paralysis for many years without taking any special precautions to exclude syphilis, and I do not remember ever having been caught operating unwittingly upon a progressive case. Occasionally one has operated deliberately upon progressive cases in adults in whom the progress of the disease appeared to be so slow as to be negligible.

In a large proportion of cases of cerebral paralysis there is some degree of mental deficiency. It need hardly be said that idiots are unsuitable for operative treatment. But mental impairment of less degree is no contraindication to treatment. Practically any spastic child can be set upon his feet and made to walk somehow, provided only that he has sufficient intelligence to try to use his legs, and it is generally agreed that the mental state of such children may be materially improved by the relief of their mechanical disabilities. Involuntary movements—athetosis, variable spasm, and associated movements—when well marked, are a contraindication to the ordinary methods of treating spastic contractures.

The treatment of spastic paralysis is operative. It is true that considerable improvement may sometimes be effected in spastic individuals by systematic training or re-education of movements. But, apart from this, non-operative treatment is useless, and I have never yet seen any permanent benefit result from massage, manipulations, or electrical stimulation. Moreover, in the majority of cases the place of re-education is after operation and not before it.

Spastic paralysis commonly gives rise to certain contractures of the limbs, and it is to the relief of these contractures that surgical treatment is almost entirely directed. The typical contractures of the lower extremity are plantar flexion of the foot (spastic equinus), flexion of the knee, and adduction of the thigh; while in the upper extremity pronation of the forearm and flexion of the wrist are most characteristic.

Spastic contracture is a tonic reflex contraction of the muscles. It disappears during deep anaesthesia and when the reflex arc is interrupted in any part of its course. This physiological contracture may persist for a long time without any permanent change occurring in the structure of the muscles. But eventually an anatomical or structural shortening is added to the physiological contracture, and the deformity becomes fixed. When structural shortening exists it must be treated by direct attack upon the shortened muscles or their tendons. But when we are

dealing with pure physiological contracture we have a choice of methods.

It is hardly necessary now to discuss Foerster's operation or posterior root section, since it has been universally abandoned as a method of treating spastic paralysis. It is, however, necessary to say something about the operation of sympathetic ramisection which was recently introduced by Hunter and Royle, and has now been given a fair trial. This operation is based upon the hypothesis that the functions of movement and posture are performed by entirely different sets of muscle fibres, and that the movement fibres are supplied by the ordinary spinal nerves, and the postural fibres by the sympathetic. Spastic paralysis being a state of exaggerated postural activity, it was thought that destruction of the grey rami of the sympathetic would cure or greatly diminish the spasticity of the corresponding muscles.

It may be said at once that the claims put forward for this operation have not been substantiated. While movement and postural activity are undoubtedly different physiological processes, they are nevertheless intimately associated with one another, and the weight of evidence is against there being an anatomical differentiation of these two functions in higher animals. As to the view that the sympathetic is specially concerned with the postural activity of skeletal muscle, the histological evidence is negative and disputed; the conclusions drawn by Hunter and Royle from experiments on animals have been severely criticized by neurologists; but what perhaps concerns us most is the fact that in the hands of others the operation of sympathetic ramisection has not given results at all approaching those claimed by Royle.

I have done this operation ten times. In about half the cases there was no appreciable effect either upon the muscular tone or upon the vascular condition of the limb. In the other half the operation was followed by vaso-dilatation of the limb and a definite but slight diminution of the muscular tone, comparable to what one would expect from the accompanying vaso-dilatation. In no case have I been able to persuade myself that it was of real benefit to the patient. This experience seems to be similar to that of nearly all others who have tried this operation in this country and in America, and similar results also were obtained in two cases specially selected from a large number of cases and operated upon by Royle in Boston in October, 1924. The operation of sympathetic ramisection, therefore, is not likely to survive long as a method of treating spastic paralysis.

For many years orthopaedic surgeons have treated spastic contractures locally by operations upon the contracted muscles or their nerves. I would emphasize the point that whether one attacks the muscles or the nerves, the principle of the operation is the same—namely, to diminish the effective action of the preponderating group of muscles. One can diminish the effective action of a muscle either by lengthening it, so that its effective range of action is less, or by destroying part of it, so that its strength of contraction is less. Good results may be obtained by either method. But I think that the operations on the peripheral nerves—known as Stöffel's operations—have some advantages over those on muscles and tendons, and I will tell you briefly what I think they are.

The correction of the typical deformities of spastic paralysis by muscle and tendon operations entails a long course of treatment, the details of which are, of course, well known to you. Briefly, in a case of cerebral diplegia, the adductors are divided and the thighs widely separated, the hamstrings are divided and the knees kept straight on splints, and the tendo Achillis is lengthened by a plastic operation. Even after excision of portions of the adductors and hamstrings the tendency to recurrence of the contractures is so great that it is necessary to keep the limbs for a considerable time in some form of apparatus with the thighs fully abducted and the knees extended. Finally, in order to prevent relapse, many surgeons have found it necessary to put these cases into walking instruments for a long time after the correction of their deformities. Now the principle of Stöffel's operations on the peripheral nerves is this. In spastic contracture we have a

powerful group of muscles in a state of tonic contraction so intense that it holds the part in a position of deformity, and prevents movement in any other direction. By destroying a sufficient part of this muscle group we abolish the excessive contraction and get rid of the contracture deformity, while leaving sufficient muscular power for all practical purposes. The simplest way of destroying muscle fibres is to cut out their nerve supply, and Stöffel's operation consists in finding the nerve tracts—usually before they leave the main nerve—and excising a sufficient portion of them.

I will not detain you with details of these operations in different regions. Suffice it to say that for adductor contracture of the thigh one resects the two divisions of the obturator nerve; for flexion contracture of the knee one resects the nerve tracts to the long head of the biceps, the semimembranosus, and part or the whole of the semitendinosus; while for the equinus contracture of the foot one resects one-half to two-thirds, more or less, of the nerve tracts to the gastrocnemius and soleus. In each case the relief of the contracture is immediate and permanent, yet sufficient power is retained to adduct the thigh, flex the knee, or raise the heel from the ground, when required. Similarly, the pronation and flexion contracture of the upper extremity may be relieved by destruction of a sufficient part of the nerve tracts to the pronators and flexors.

To Stöffel we owe the development of the "cable theory" of nerves. He demonstrated that in the main nerve trunks of the limbs the various nerve tracts maintain their identity and independence at least for a considerable distance, and that the cross-section of a large nerve is fairly constant in any given situation. So that, given a knowledge of the position of these tracts, we can pick out and isolate from the main nerve trunk the nerve supply of any required muscle group, and we can then destroy as much or as little of it as we please. The ease with which any main nerve trunk can be exposed in a limb, and the fine adjustment and variation that are possible in dealing with the nerve tracts, give to this operation both a simplicity and an adaptability that are, I think, unattainable by any other method of operating.

As examples of variations from what one has come to regard as the typical operations, I would instance cases in which there is severe flexor spasm of the toes, making walking difficult and painful; others in which there is peroneal spasm causing pronounced eversion of the foot; and yet others in which there is persistent internal rotation of the thigh. In each case the contracture is disposed of by resecting a sufficient part of the appropriate nerve tract—the flexor tract to the toes on the deep surface of the internal popliteal nerve, the peroneal tract in the middle of the external popliteal nerve, and the tracts to the internal rotators of the thigh in the superior gluteal nerve.

I need hardly remind you of the consequences of destroying the nerve supply to a muscle. The muscle immediately becomes completely and permanently paralysed; it is pale, flabby, and atrophic; it has no tendency to shorten; on the contrary, it is very easily stretched, and, when stretched, it stays elongated and relaxed. And this is the outstanding feature of Stöffel's operation as compared with operations directly upon muscles and tendons: that the effect is immediate and permanent; there is no tendency to recurrence of the contracture in the paralysed muscle fibres; there is therefore no need to keep these patients in abduction frames or other apparatus; they can be got up almost immediately after the operation; and they require no walking instruments afterwards. In a word, Stöffel's operation abolishes the prolonged mechanical treatment of spastic paralysis, and in particular the use of splints and apparatus.

Some of these statements, which I have made before, have already been criticized, particularly the statement that the results are immediate and permanent. So that I would like to add that I have seen recurrence of deformity after Stöffel's operation—for instance, equinus deformity of the foot after operation on the internal popliteal nerve. But I do not blame Stöffel's operation for this—I blame myself, for it is due either to faulty judgement or to faulty

technique. Usually the recurrent deformity is a structural shortening of the muscle, and it means that sufficient care has not been taken to exclude the beginning of structural change before doing Stöffel's operation. Even a slight structural shortening will inevitably increase and entirely spoil the effect of the nerve operation. Other cases of recurrence are due to too little of the nerve tracts having been destroyed. For adductor contracture Stöffel recommended that the anterior division only of the obturator nerve should be removed in mild cases, and both divisions in severe ones. But for many years I have removed both divisions as a routine, for here, as elsewhere, the tendency is to do too little rather than too much. And I prefer Stöffel's operation in the thigh to the route through the abdominal wall, because it is a minor operation which divides no muscles and is obviously less disturbing to the patient.

With regard to the end-results, it must be remembered that spasticity is but one of the disabilities of cerebral paralysis. Even after the removal of their contractures the severer cases never walk quite naturally, and they are apt to be awkward and ungainly. Yet, to take a child who cannot even stand upright, and to put him on his feet and get him walking somehow, is at least a result worth having; while in less severe cases there is often a very striking improvement in stability and locomotion. Fortunately, with the exception of idiots, every child instinctively tries to use his legs, so that the only after-treatment required is practice and encouragement, which in most cases can quite well be given at home.

In the case of the upper extremity the conditions are different. A patient with one sound arm and one disabled one will use the sound arm for everything that he can do with it, and there is hardly anything in the ordinary daily routine of life that cannot be done quite well with one arm. So that in hemiplegics at least there is no natural incentive to use the affected arm after operation, and we depend much more upon the patient's intelligence and co-operation in order to obtain a useful result. Still, some of these patients do show a very considerable improvement as regards function, and the cosmetic result alone is sometimes worth having, for the characteristic pronation-flexion contracture is an unsightly deformity, and the appearance of the limb is often much improved by the relief of these contractures.

In conclusion, I would submit that Stöffel's operation is the best method of treatment which has yet been devised for the relief of spastic contracture.

The actual operation in each region is quite a minor operation and easy of performance.

It admits of a degree of precision and adjustment to the needs of individual cases such as cannot be obtained in any other way.

Its results are immediate and permanent.

The very nature of the resulting intentional paralysis makes recurrence of the contracture impossible.

Therefore, prolonged after-treatment and the use of splints or other apparatus are unnecessary.

#### GENERAL DISCUSSION.

Dr. J. BEATTIE (London) said that he had come to demonstrate some cinematographic records of experiments performed on seagulls and goats by the late Professor John Irvine Hunter and Dr. Norman Royle of Sydney. In the seagull it was easy to cut the sympathetic connexions of the wing with the spinal cord without interfering in any way with the somatic nerves, afferent or efferent. After this operation had been performed the bird appeared to be normal at first sight, but if the wings were carefully examined it would be seen that the wing which had been deprived of its sympathetic connexions with the spinal cord was slightly lower than the wing on the unoperated side. When thrown into the air this bird seemed to fly in a perfectly normal manner, except that it tended to fly in a left-handed spiral. After flying for about a hundred yards it came to earth with the affected wing in a flaccid condition. This wing was exhausted and the muscles were undoubtedly in a state of complete fatigue. After allowing time for the effects of fatigue to

pass off the experiment could be repeated and the same effects produced. It was therefore idle to pretend that the sympathetic system was devoid of influence on muscular activity. In another record a goat was shown deprived of the lumbar portion of the left sympathetic cord. After decerebration rigidity developed in the four limbs, but the left hind limb soon tired and became flaccid. This was a definite and constant result of this operation, and it showed that removal of the sympathetic influence did produce a definite effect on the limb muscles. The third record showed the effect of the removal of the bird's corpus striatum in producing a spasticity of all the limbs analogous in many respects to Parkinsonism in man after encephalitis lethargica. Dr. Adie, in his opening statement, while admitting that sympathetic nerve fibres might reach striped muscle fibres and might exert an important trophic influence on them, had said that the evidence at present available did not support the notion that the sympathetic played any part in the regulation of muscle tone. He had also stated that the higher centres from which the impulses passed to reach the sympathetic were situated at the level above the point of election for the section that produced decerebrate rigidity. Dr. Adie considered it certain that complete ablation of the sympathetic system had no effect upon decerebrate rigidity. The records shown seemed to suggest that the denial of any influence of the sympathetic on muscle tone required reconsideration. Dr. Adie had made the further claim that the centres controlling the sympathetic system were high up in the nervous system and must necessarily be cut when the operation for effecting decerebrate rigidity was performed. Here again the facts had been definitely established by two independent series of investigations. In the first place, Professor Hunter had been able to demonstrate that the maintenance of tone was not wholly dependent on Deiters's nucleus, which many years ago Dr. Thiele had proved to be concerned in the causation of decerebrate rigidity. Professor Hunter had been able to demonstrate experimentally in the goat that another centre was present which it was necessary to eliminate before complete flaccidity could be induced after cutting off Deiters's nucleus. This centre was in the formative reticularis a short distance away from Deiters's nucleus in the lower part of the pons. Without any knowledge of Professor Hunter's work, Drs. Bernis and Spiegel in 1925, using the cat and the dog for their experiments, had arrived at precisely the same conclusions. They affirmed that, although the vestibular nuclei played an important part, they were not the only centres for static innervation in the rhombencephalon. Unilateral destruction of the vestibular nucleus and its associated cell groups did not cause a complete loss of tone in the decerebrate animal. Alongside the vestibular nucleus there was a large-celled nucleus in the formative reticularis which played a part as a centre for static innervation. Fibres descended from it in the antero-lateral column of the spinal cord.

The influence of the cerebellum in the regulation of tone (which they had stated could be proved by the stimulation of the anterior lobe) expressed itself in a diminution of the tone of the extremities, and did not act only through the superior cerebellar peduncle. A second efferent system flowed out of the cerebellum to the oblongata and could be demonstrated in the restiform body; in all probability it passed through the tractus fastigio-bulbaris. In addition to the cells of origin of the pyramidal tract, not only the frontal but also the temporal cortex played important parts as places of origin for tonus-regulating systems. In quadrupeds like the carnivora the influence of this system was very slight. In face of these very definite conclusions it was difficult to discover any cogency in Dr. Adie's second point.

In attempting to apply to the human subject the results made on mammals other than primates, the utmost caution was necessary, because the nature of the factors regulating tone in man and his nearest relatives differed from those of members of other mammalian orders. This fact had been emphasized by Magnus and his colleagues, and was asserted once more by Bernis and Spiegel. A somewhat analogous, although by no means identical, cephalization occurred in birds. It must be remembered that their

corpus striatum represented not only the homologue of the mammalian corpus striatum, but also of the neopallium. Excision of the corpus striatum exerted a very definite influence upon muscle tone, to which Professor Hunter had called attention in the lectures published in the *BRITISH MEDICAL JOURNAL* in January, 1925. The cinematographic records had shown the effect of the extirpation of the corpus striatum in the bird. The effects were in many respects similar to the post-encephalitic Parkinsonism found in man.

Mr. S. W. DAW (Leeds) considered Dr. Adie's classification of the causes of spastic paralysis to be very complete; as surgeons they should be grateful to him for emphasizing the existence of the various progressive types which were unsuitable for operation. At the same time Mr. Daw agreed with Mr. Bankart that such cases were rarely presented for surgical treatment; when seen, there were usually definite danger signals. Mr. Bankart many years ago had called attention to the value of Stöffel's operation in spastic paralysis, and Mr. Daw was convinced of the great superiority of operations on nerves to those on tendons in suitable cases. It was well known how tedious was the prolonged fixation of the lower limbs in the position of correction; the results of nerve operations were claimed to be immediate and complete. Moreover, the process of muscle education was much simplified and could be begun in a week or two. In cases where there was commencing or pronounced contracture of muscle the methods of nerve section and muscle lengthening should be combined. The speaker emphasized the value of the method of lengthening the soleus muscle after division of its aponeurosis as an alternative to lengthening the tendo Achillis. The procedure could be carried out without making a breach in the continuity of the muscle-tendon unit. Turning to a consideration of the upper limbs, where the deformity was usually unilateral as part of a hemiplegia, he did not think that Stöffel's operation made the same logical appeal. In this case it seemed reasonable to make, if possible, a redistribution rather than a reduction of power. The flexors and pronators practically always predominated and the power of the extensors was reduced. Generally speaking, Mr. Daw had found it satisfactory in suitable cases to perform an operation very much as described by Sir Robert Jones for irrecoverable posterior interosseous nerve injury—namely, to divide the flexors of the wrist and insert their tendons into those of the extensors of the thumb and fingers. At the same operation the pronator radii teres was divided and inserted into the extensor tendons of the wrist. The least that could be expected was a greatly improved cosmetic effect, but there was no doubt that function of the hand might also be decidedly bettered. Even in the presence of athetosis of not too severe a kind this operation was worth consideration.

Mr. NAUGHTON DUNN (Birmingham) defined three factors in spastic paralysis: (1) the mentality of the child, (2) the degree of spasticity of the muscles, and (3) the voluntary control which might or might not be present. These would vary in each individual case. It was agreed that the principal means of helping these children was by re-education in the use of the limbs, and by some operation to diminish the spasticity which interfered with function. In the case of the child whose mentality was severely impaired no operation or re-education was likely to be helpful apart from any procedure which would alter the position of the limbs and so facilitate nursing. In other cases where the child could understand the mother or the remedial gymnast, re-education of control of the limbs was often most helpful, and should be continued until the child itself began to make some effort to use the limbs for the purpose for which they were intended. An operation to reduce the spasticity of certain groups of muscles might then be most helpful. The type of operation, whether lengthening the muscles or diminishing their nerve supply, did not seem to be of great importance. The speaker's usual practice was to operate on the nerve supply of fleshy muscles, such as the obturators, the pronator radii teres, and the gluteus maximus, simply because it was easier. In

## SPASTIC PARALYSIS.

DEC. 25, 1926]

the case of muscles with direct tendinous insertion, such as the tendo Achillis, biceps, and ulnar and radial flexors, he thought a more accurate and satisfactory result was obtained either by their division or elongation. In the case of spasmodic deformity of the wrist and hand he had had good results from tendon transplantation in selected cases, but each case required very careful observation as to the degree of muscle control present. A period of splintage and re-education was often an essential preliminary to operation in these cases. As a rule, unless the patient developed voluntary control of the flexors of the fingers and thumb, operations to correct the position or control of the wrist, and the extensors of the fingers and thumb, were not likely to be helpful. The question of simply dividing the wrist flexors, or transplanting them, would depend largely on the voluntary control of these muscles. If they remained in uncontrolled tonic spasm they were better divided, the position of dorsiflexion of the wrist in this case being maintained by passing the forearm of the radial and ulnar extensors through the forearm bones, so that they might act as ligaments to maintain dorsiflexion of the wrist. In other cases where voluntary control of the wrist flexors was present and the extensors were weak the flexors of the wrist might be transplanted with advantage.

Mr. H. A. T. FAIRBANK (London) said that in the cases which came to the surgeon it had been stated that there was an exaggeration of the postural reflex which normally maintained the upright position of the body and paralysis of reciprocal innervation. Did these explain the development of the deformities? Admitting that the position of the legs was generally one of extension, why was flexion of the knees, and not uncommonly also of the hips, a feature of the cases, when the hamstrings were not the seat of spasm, and not uncommonly also of the hip, a feature of the cases, when the hamstrings were not the seat of spasm? Mr. Fairbank agreed with Stöfel that any spastic deformity could be produced if the limb was held in the requisite position sufficiently long. All the muscles were affected more or less, but the stronger groups, or those acting at a mechanical advantage or helped by gravity, gained the day and produced the deformity. If these stronger muscles had their tendons cut and after treatment was injudicious, the opposing muscles became just as spastic and deformity-producing as the original group. Gravity was important in producing equinus; the ulnar deviation of the hand was also due to gravity. The exact extent of the lesion played a part in determining the direction of deformity; how otherwise could an explanation be found of internal rotation occurring in some and not in others? The common adduction deformity was due to the mechanical advantage which the adductors possessed over the abductors. Involuntary movements, when well marked, were a contraindication to operation, but in the milder cases this was certainly not invariably so. Cessation of a particular temporary spasm by operation might materially aid the function of a limb. Massage was useless, but as regards systematic training there arose the question of the age at which operation was advisable, about which nothing had been said. Patients were seen showing signs of walking soon after the age of 2, for instance, but these were best left till at least 3 before operation. In the meantime training in walking could be carried on, and after this time training in walking could be carried on, and after this delay it was easier to determine exactly what deformities required operative treatment. Why did some cases develop anatomical contractures early, while in others this complication was surprisingly late?

As to the methods of treatment, the speaker agreed that two only were worthy of consideration—namely, division or lengthening of tendons, and Stöfel's operation. He thought each deformity must be considered by itself. While Stöfel's operation was best for adductor spasm, the open lengthening of the tendo Achillis was the best for equinus. For the knee flexion in younger children he chose Stöfel's method; in the older children the Stöfel operation with tenotomy. He preferred the extraperitoneal route, as introduced by Mr. Tyrrell Gray, for excision of the obturators. It was no more severe an operation than stacking the divisions of this nerve in the thigh, and had the advantage of being further removed from the perineum. For internal rotation he preferred to cut the superior

gluteal and its branches above the trochanter rather than further back. For equinus he was strongly inclined to open lengthening of the tendo Achillis, after an experience of Stöfel's operation on the internal popliteal in over sixty instances, in a large number of which the tendon operation had to be resorted to later. He agreed with Mr. Bankart in blaming the tendon operation was the better, the convinced him that the tendon operation was the better, the more certain and lasting in its results, and therefore the easier. The tendo Achillis should be united after division so that the tendon was pulled on just before the foot came up to a right angle rather than at a right angle. If the Stöfel operation was in the least insufficiently performed a deformity could develop later. To avoid this it must be necessary to destroy more nerve fibres, and then came the dangerous possibility of destroying just too much. He had seen patients operated upon by the Stöfel method at 3 or so without any contracture, and though he had been entirely satisfied with the results for a year or two, yet the patients had developed equinus again later. He preferred to deal with the muscular branches as well as the continuation of these upwards rather than the bundles in the main nerves, when using the Stöfel method. As to the length of nerve, it was necessary to excise to prevent regeneration, particularly when only a portion of a trunk was being dealt with, he always cut out at least an inch, and often much more, in the case of the obturator nerve; yet in two cases, one bilateral, making three nerves in all, he had seen the adductors regain their power after several months. In the bilateral case he operated a second time, exposing the nerves in the thigh and finding them and the muscles healthy and responding to electrical stimulation. There was no sign of an accessory obturator nerve. Since there was nothing on the lateral wall of the pelvis which could be mistaken for the obturator nerve, apart from the fact that unmistakable contraction of the adductors occurred when the nerve was seized and cut, he could not believe that he had failed to excise the nerves, and he was forced to the conclusion that he did not excise a sufficient length of them. In another case he saw recovery of the anterior parts of the glutei after excision of the superior gluteal nerve, but in this he admitted that the length of nerve excised was much more likely to be small. As to splints, there were cases where these were necessary for a time. In the case of the foot, he thought a rectangular tin shoe should always be used for at least a year after operation, and daily passive dorsiflexion to the full extent be practised for an indefinite period. This was necessary because gravity favoured a return of the deformity, which was not the case with the other common spastic deformities. He believed that Tubby's operation for pronation was founded on a misconception of the movements of the radius during supination; the results were not good. He preferred the Stöfel operation on the branches of the median, with simple division of the pronator radii teres, if this was contracted. Speaking generally, the results of treatment of a spastic arm were most disappointing, except as regards pronator spasm.

Mr. H. TYRRELL GRAY (London) considered that injury at birth was undoubtedly responsible for a large proportion of cases of cerebral diplegia; but there remained a considerable number in which no such cause could be traced. One of the worst cases in the experience of the speaker was shown to be due to an extensive congenital defect of the cerebrum on both sides. If it were borne in mind that so many congenital deformities, such as wryneck, congenital talipes, hare-lip, and cleft palate, were associated with defects in the central nervous system, it was only reasonable to allow that a certain proportion of cases of cerebral diplegia originated in the same manner, independently of injury at birth. The speaker thought that the tendency to improvement in some instances, be due to compensation by unaffected parts. In support of this but this feature might, in some instances, be due to compensation by unaffected parts. In support of this body afforded numerous examples. In support of this view the case of hare-lip and cleft palate was quoted. Here defective means of producing certain sounds were compensated by developing the powers of mimicry of normal speech. The parrot was quoted as a notable example of

such close mimicry. If such views were correct the degree to which the desire and ability to walk could be inculcated indicated the extent to which surgery could be helpful, aiming only at removing the mechanical disabilities. Though it was true that the power to walk was an aid to mental development, the main indication for interference was the inclination to walk. Following an operation such as the removal of mechanical disability, education was of paramount importance, and was the keynote of a good result. Of the different types of operation advocated, tenotomy and excision of muscles were practically extinct, and, though Foerster's operation had long been abandoned, the speaker, from an experience of six cases, could not help regretting that an operation which had given such satisfactory initial results had been followed by relapse in every instance. Stöffel's operation, alone or with tendon slide, was the method of choice. The value varied in different regions. For adductor spasm resection of the obturator nerves was the best procedure. He still adhered to the abdominal (extraperitoneal) route, which he had practised for the last seventeen years. For flexion at the knee he performed Stöffel's operation with, in some cases, lengthening of tendons also. He was inclined to agree with Mr. Fairbank that, for equinus, tendon lengthening was usually necessary, whether Stöffel's operation was performed on the internal popliteal nerve or not; and that the tendon operation alone was frequently the most satisfactory procedure. But whatever views were held as to surgical details, the one essential was patient post-operative education.

Dr. M. R. WALSHE (London) said that since Dr. Beattie was again raising the fallen standard of sympathetic ramisation as a scientifically based procedure it was necessary to be clear about the ascertained facts, anatomical and physiological, upon which this operation was based. Dr. Beattie had retired from the original position taken by Hunter and Royle, and had, as he understood, allowed that in the human subject the operation was without result; inferring from this that the nervous processes underlying regulation of muscle tone in primates must be different from those obtaining in the lower mammals. All the physiological and clinical evidence available, without exception, indicated that the regulation of tone and of posture was essentially the same in man as in the lower animals in question. Dr. Beattie's difficulty in having to allow the futility of sympathetic ramisection as an operative procedure to overcome spasticity in man was not to be escaped by this entirely speculative proposition. Returning to the evidence brought forward in support of the view that muscle tone was a function of a special element in the striated muscle fibre and was controlled by the sympathetic nervous system, it seemed a reasonable conclusion that the histological evidence was incomplete and inconclusive, and that the existence of a general sympathetic motor innervation of striated muscle was still an open question. As to the experimental evidence, however, the question was not an open one. Not only was it not proved that there were two distinct components of muscle tone, but it was possible to go further and say that Hunter and Royle's experiments on goats and birds seemed to indicate that there were no such separable components and that sympathetic innervation was not in question. Even if the condition pictured in the cinematograph photographs of the goat shown by Dr. Beattie could be regarded as a constant result of uncomplicated sympathetic ramisection in this animal, it did not justify the theoretical conclusions drawn therefrom by Hunter and Royle and provided no evidence of the existence of a "contractile" component of tone; it seemed, indeed, to exclude such a possibility. In respect of the cinematographs of birds, an even more conclusive objection to accepting Hunter's interpretations was that similar, more extensive, and more carefully controlled experiments had been performed over twenty years ago by Trendelenburg without impairing either wing posture or the power of flight. In the absence of anatomical controls it was not possible to say what had so disabled Hunter and Royle's birds, but there was no reason to suppose that posterior root section was adequate to do so.

In short, on every count the evidence advanced to prove that muscle tone was controlled, either wholly or in part, by the sympathetic system was defective.

Dr. E. W. N. HOBHOUSE (London) dealt with the common and non-progressive forms of spastic palsies—hemiplegia and diplegia—with special reference to their treatment in infancy and early childhood. He thought that Dr. Adie had made out a good case for the view that many spastic diplegias were due to birth trauma. The analogy drawn between cerebral diplegias and lesions of the superior longitudinal sinus was certainly very suggestive. Two types were probably included under the name of "Little's disease" which might have different pathogenesis. There was a type which was really a quadriplegia, and certainly corresponded very closely with the superior longitudinal sinus lesions, except that it was fairly common to find flexor contracture of the hand in them. There was also a type with a paraplegic distribution, in which the spasm was not maximal in the distal part of the limb, but was particularly marked in the adductors. Dr. Adie remarked that a primary neuronic degeneration was usually progressive, but it might be that the process here was an agenesis rather than a true degeneration.

As to the treatment of these cases Dr. Hobhouse believed that the problem was quite different from that of adult spastic palsies, and that if the cases came to notice in infancy or early childhood, it was possible to prevent, in many of them, the spastic states which required operative measures. Putting on one side the children with real mental impairment, frequent fits, or any form of hyperkinesia, he thought that there was a wide field of non-operative treatment for the others, and that the results were good in nearly all the hemiplegias and a large number of the diplegias. Mr. Bankart said that the condition was essentially incurable; it certainly was so as far as the affected neurones were concerned, but in the infant, as regarded function, he was not convinced. The infant's brain seemed to be a very plastic organ, capable of developing a large number of new reactions. Personally he was open to the idea of the occurrence of vicarious action of other parts of the cortex, though he recognized that this was quite an unestablished hypothesis, at any rate in the higher animals. But he did believe that in any child in which new reflexes could be conditioned new voluntary movements could be developed, and there seemed to be no reason why, if this could be done, new inhibitory impulses should not also be brought into action, with consequent relief of spasm. In practice, at any rate, he had noticed that if active movements could be re-established from an early age, a condition of severe spasm seldom developed, and no contractures occurred. This might be partly owing to some adjustment of the length of the growing tendons, taking place. Mr. Bankart said that he had seen no good effects of massage, manipulation, or electricity. Dr. Hobhouse agreed with him about the first two, but would go much further in the third. He believed that the faradization of spastic muscles was an absolutely irrational proceeding which was the principal cause of most of the severe spasms and contractures in these children. It had often been condemned by specialists in electrotherapy, and he had never heard a medical man defend it, but the fact remained that the relatives clamoured for it and usually obtained it. He rarely met with a severe case in a patient of over 4 years of age in which it had not been used; on the other hand, he rarely saw a high degree of spasm developing in a child who had not received it.

Dr. Hobhouse's two main principles in treating an early case were to keep the child from electricity and to educate active movement. In a diplegia the great object was to get the child using the legs as soon as possible. He had found that a wheeled frame with adjustable supports under the axilla was of great value in getting the child to learn to walk, and that later on such contrivances as horse-tricycles and kiddie-cars were very useful. But the most surprising results had been in the hemiplegic arm. For this there was only one line of treatment that he had found of any use—namely, to tie up the sound one. In dealing with an adult hemiplegic—particularly with the type of adult most liable to hemiplegia—the difficulties in doing

this were very considerable, but in the infant it was quite simple if the intelligent co-operation of the mother and nurse could be obtained, and the rapidity with which voluntary movements developed in the free paretic arm was most remarkable. In children in whom a high degree of spasm had developed he had certainly seen Stöckel's operation yield the best results, because this could be followed by the simple re-educative measures mentioned, instead of by immobilization.

Dr. W. F. Menzies (Cheddleton), referring to upper neurone defects, said that such terms as contraction and relaxation, flexion and extension, agonists and antagonists, voluntary and automatic, should be regarded as of comparative value only. Nerve stimuli arose from the energy of neurones which had only one action—namely, discharge, sudden and complete, on the "all or none" principle; then there followed a latent period and slow recovery. These neurones discharged only in response to an afferent stimulus, exteroceptive, enteroceptive, or proprioceptive. They discharged like a continuous and unending machine-gun bombardment from conception to dissolution, countless millions of them, but there must be a lower mechanism somewhere which marshalled them into orderly volleys, passing along the nerves at various rates, usually about fifty a second, for both twitch and tonus were in fact tetanic. Only a few millions of the countless myriads discharged at once, and these formed patterns of synaptic resistance. If an impulse was strong more neurones were used, and the paths of resistance determined whether a discharge should eventuate in flexion or extension or reciprocal movement or partial relaxation—what was plastic tonus—or what not. A great reflex reserve battery—the olivo-cerebello-pontine—was ready to reinforce certain habitual postures, such as reflex standing in man, seen at its highest intensity in decerebrate rigidity. The only phenomenon which produced a really widespread discharge was the epileptic fit, which resulted in severe neuronic exhaustion—coma; yet it scarcely affected such ancient mechanisms as those in the medulla.

The patterns of synaptic resistance in the cerebral cortex had been worked out by the Pavlov school, but these paths were fairly modern, and concerned mostly the infragranular layers in the higher vertebrates. They were not, of course, so recent as those which represented the cultural development of man, those essentially supragranular paths which were termed "mind," but they were infinitely more modern than the patterns followed in the medulla, that portion of the central nervous system which had remained comparatively stable since the epoch of the segmental invertebrate. Roughly speaking, there were five physiological levels of movement and posture: supragranular, where the involuntary or directed movements were initiated, the infragranular, most used in the semi-automatic patterns of everyday life; the thalamo-striatal, where automatic ancestral movements, conscious and unconscious, were worked out; the spinal, given over to defence reflexes of a massive type; and the brain stem area.

In aments there were all degrees of cortical underdevelopment. If the supragranular layers alone were affected the children could walk and play and learn to speak only when supragranular involvement was fairly slight, for speech was a very involved system of any great extent defective the children could never apply symbolism. If the infragranular layers were to be taught personal cleanliness; many of them could never walk. In the normal child the Betz axons, which arborized widely round the small granular cells of the cord by means of their very numerous collaterals, were not fully myelinated at birth. Standing was impossible, and there was no rigidity. In many aments myelination was late, and owing to supragranular defect the desire, or libido, for directed movements did not exist. These patients could be taught to walk and grasp by educational methods. If ultimate myelination remained incomplete, through partial agenesis of infragranular layers, various deformities arose, lower mechanisms being imperfectly controlled. It was a curious fact that when a start was made in teaching a perfectly plastic-

limbed child to stand, spasticity commenced to appear years earlier than in others who had been left alone. Thus deformities were originated, not because certain patterns of movement were less under the control of higher levels, were stronger than others, but because certain patterns in a general sense the more cortical and striatal the control, the more the spastic postures tended towards extension, whereas in advanced cases of paralysed aments all the limbs were flexed and rigid. This rigidity was indicative of spinal sclerosis. The gradual deterioration was largely regulated by phylogenetic antiquity, and it was interesting to observe the simulacra of ancestral postures—fragments of the standing mechanism, as in talipes equinus, which originated when the race came down from trees and emerged from the forests; climbing mechanisms of an earlier date, as in the scissors gait or talipes varus, when caudal extremities were used to grasp boughs; flexor attitudes, when early vertebrates grovelled on the ground. But always the hand had differentiated least, and flexor rigidity prevailed.

After some years of endeavour with ordinary idiots, Dr. Menzies began to think that something might be done for the paralysed and those with spastic deformities; Mr. Mitchell Smith was now treating such cases by various appropriate methods. It was hoped to get them progressively younger as time went on, so that violent methods might not be necessary. The first task was to combine hand, ear, and eye—seeing objects, grasping them, trying to pull at them. They had little bells and bright coloured objects dangling within hand reach, and rings by which the child was encouraged to pull himself up. Then they got him on to his feet, holding on by a bar, and which the child was encouraged to pull weight on the legs, and eventually encouraged him to bear weight on the legs, and so, aided by the nurse, to walk. If tendon transplantation was required the surgeon must be careful as the movement aimed at—not, for example, to attach a muscle whose habit was flexion to a group of extensors. The most useful movement in the hand was the grip, in the shoulder adduction, extension, in the lower limb extension at hip and knee and a right-angled foot. The child learnt to substitute healthy neurones for those missing. It was wonderful to watch how musculo re-education improved the whole mental outlook, but the trouble was to stimulate the desire to try, for the instinct which helped so greatly in dealing with normal children was lacking in the ament.

Why did effort tend to produce earlier spasticity? The evidence concerning the existence of a fronto-pontine tract—by which Dr. Menzies presumed intermedio-precentro-pontine was meant—was contradictory, but the presence of a cortico-striatal connexion seemed probable in lower vertebrates. It was not necessary to presume either of these in man. Tone was a component of all reflex systems, and when older patterns were imperfectly controlled from higher levels they naturally assumed their inherited biological modes of action, even in the isolated cord. With regard to the sympathetic supply to skeletal muscle, it was realized how predominant was the influence of the afferent sympathetic in determining the feeling-tone arising in plain muscle. Could they deny the same emotional value to it in the case of striped? They had an example in normal life when "fidgets" were relieved by voluntary movement. Might not the affected muscles of the ramisectioned gull or goat lose their "will to endeavour" by the cutting of the efferent grey rami? This was a matter with which the efferent (the cortex) had little to do. The dilatation of arterioles brought about by injury to the afferent sympathetic was competent to produce the final fibrous rigidity. An instance of what he conceived to be the influence of the sympathetic fibres in choriform movements, who could not stand, but showed no hypertonus. In the hope that the movements might diminish if he could learn to stand and walk, both hips and both knees were placed in plaster in extension. He went downhill so fast that he nearly died, but recovered in a few weeks after release. They were now experimenting with one joint at a time, but these cases were at best decidedly unfavourable.

Mr. A. ROCYN JONES (London) said that one striking feature about the cases considered suitable for operation

was their great mental improvement when once they found themselves able to walk with some confidence. Hospital school teachers stated that not only was the child's walking improved, but that the intelligence was quickened and the brain became more receptive to instruction: the child took a new interest in life. Of the operative procedures Stöffel's was undoubtedly the operation of choice, but there were many cases in which a combined nerve and tendon section produced the best result. For tendo Achilles spasm with contracture section of the branches of the internal popliteal nerve with open elongation of the tendon at the same time produced the best result, but the elongation should only be such as to permit the foot to dorsiflex barely to right angles with the leg, as Mr. Fairbank had mentioned. If the foot passed beyond a right angle at the time of operation there was great danger of a calcaneus deformity subsequently. The adductor spasm seemed to be the most difficult to correct permanently. Both branches of the obturator nerve should be cut, and this could be done without much difficulty on the inner side of the thigh through a four-inch skin incision. The extraperitoneal route seemed hardly necessary. It was often an advantage to remove about an inch of the tendon of the adductor longus at the same time. As for the upper limb, the functional result of operation in infantile hemiplegia had been disappointing. Both tendon transplantation and nerve section had singularly failed in producing a more useful hand. Either method would produce a good cosmetic result; instead of the flexed wrist and clenched fingers the hand appeared more natural after operation, but even so, inco-ordination and lack of precision in finger movements were unaltered.

Mr. A. H. Todd (London) hoped he would not be thought retrogressive in thought and doctrine if he pleaded for the older operation of open tendon-lengthening. It appeared from the discussion that Stöffel's neurectomy was in high favour in the treatment of spastic cases at the present time; but he claimed that the older operation still had a very definite place in their surgical armamentarium, and should certainly be retained. Unless he was much mistaken, it was likely to come into its own again when the present vogue of fashion had somewhat subsided. There was no real reason why the Stöffel operation should be more effective than tendon-lengthening, since the object of both operations was the same—namely, the physical weakening of the affected muscles. The whole question turned upon the way in which the operation was performed; lengthening, if efficient, could reduce the physical power of a muscle quite as much as division of its nerve supply. One trouble was that tendons were often not lengthened enough; it must be remembered that these patients were anaesthetized, and that when the effect of the anaesthetic had passed off the muscle and tendon would be very much tighter than they were when their excessive tone was wholly abolished by the effect of the drug. One great advantage of the tendon-lengthening operation was that its effect was absolutely precise, whereas even the most practised exponents of the Stöffel operation had admitted that they had to trust more or less to luck to produce the exact amount of weakening desired. Recently an orthopaedic surgeon of one of the big London hospitals had stated that, while he always performed the Stöffel operation for the adductors and the hamstrings, he always performed open tendon-lengthening upon the tendo Achilles; he naïvely admitted that he did so because he could be quite certain of the effect of the tendon-lengthening. It would surely be logical to operate in a similar manner upon the hamstring tendons, taking care, however, to do enough. Mr. Todd agreed that at the ankle it was desirable to bring the foot to a right angle, and no further, but at the knee the common fault was to lengthen the tendons too little. In the groins the complete excision of three inches or more of the whole adductor mass of muscle was not too much, and gave an excellent effect. As regards the alleged length of after-treatment necessary after the tendon operations, he denied that this was any greater than that required after neurectomy, provided that the operation was efficiently performed. A great deal of the tendency

to contracture at the hip and knee was due, not to the muscles and tendons at all, but to the capsules of the joints, and it was these structures, and not the muscles and tendons, that took so long to stretch in the after-treatment. When contracture was considerable a necessary and integral part of the open operation should consist in capsulotomy. In the case of the knee this could be easily performed by means of one long vertical median incision, the main vessels and nerves being identified and swung, first to the right and next to the left, the capsule being completely divided in a transverse direction and then fully stretched. It would be found that after this operation the knee became completely straight, and remained so, without any tendency to recurrence of flexion. In the case of the hip he had tried various incisions, and found that the best, upon the whole, was one running parallel with Poupert's ligament, but about an inch below it; the various muscles in front of the hip-joint were completely divided, and the whole of the anterior aspect of the capsule of the joint also. The limb was then put up in hyperextension for a short time, and no recurrence ensued.

As regards the results of operation, and the after-treatment, it must be remembered that one important factor was the release of the extensor muscles from over-stretching. After operation the extensors tended to improve spontaneously, but everything possible should be done in addition to cultivate their power by means of suitable exercises and massage. The speaker agreed in condemning the use of electricity in spastic cases; parents always clamoured for it, but many children had suffered much from the ignorant misuse of a faradic coil. He regarded electricity in these cases as being not merely useless, but actually prejudicial. As far as the upper limb was concerned, he had never found any good result from the transplantation of the pronator radii teres muscle with a view to converting it into a supinator; he would regard any possible good that might result from that operation as being due to the subtraction of a pronating force, rather than to the addition of a supinating one. He thought that, apart from the use of a digitated cock-up splint for keeping the wrist and fingers extended, surgical treatment could do very little for the upper-limb affections; but very much could be achieved by the constant educational efforts of a keen parent. He was accustomed to tell parents that everything depended upon their own efforts: they must constantly encourage the child to use the affected limb, and not to follow his natural tendency to discard it in favour of the normal limb. Toys which necessitated the simultaneous use of the two hands were invaluable; such as a wheelbarrow, building bricks, and knitting-needles. They ought to consider seriously whether the present stereotyped treatment was right. They were terribly prone, as a profession, to go on carrying out orthodox treatment, simply because it was orthodox, without stopping to think whether the fundamental principles upon which it was based were right or wrong. In a discussion at the Royal Society of Medicine a well known neurologist had said that the whole practice of orthopaedic surgeons and corrective movements for the the spastic muscles was wrong; he constantly stretching these muscles they were sent into a condition of still greater spasm, and thus much was done to produce the very conditions which were subsequently treated by tenotomy and the like. He suggested that, on the contrary, they ought to give gentle, soothing, stroking movements to these muscles, if possible under running water. The whole question ought to be seriously reconsidered *ab initio* and a decision taken.

Dr. N. B. Caron (Liverpool) regarded most cases of spastic diplegia as the end-results of intracranial birth trauma, and urged the importance of recognizing this condition in the newborn infant, in order that immediate treatment, especially by lumbar puncture, might be instituted. While adding his tribute to the remarkable results of orthopaedic surgery in helping a damaged body to function more efficiently, he maintained that the prophylaxis of birth trauma was an obstetrical problem, and its essential treatment the duty of the paediatrician.

## Presidential Addresses.

### TREATMENT BY DRUGS:

#### A DIP IN A GENERAL PRACTITIONER'S TOOL-KIT.

DELIVERED BEFORE THE BIRMINGHAM BRANCH OF THE BRITISH MEDICAL ASSOCIATION

BY

H. GUY DAIN, M.B.LOND.,

PRESIDENT OF THE BRANCH.

THE choice of the subject for the presidential address to a Branch of the British Medical Association has in its time, I feel sure, been the cause of much searchings of mind or heart, whichever we prefer to consider the real seat of anxieties and the like. For the specialist in some subject or subjects it is possibly less difficult; but when a man has been in general—very general—practice for many years he has been compelled to familiarize himself with numberless questions and subjects, and at the same time prevented from becoming expert enough at any one to find material for a presidential address. I have found it the more difficult because on this occasion I did not want to drag in my particular "King Charles's head" by addressing you on anything to do with National Health Insurance, or, indeed, any other medico-political subject.

There is, however, one question very much in evidence at the moment. I refer to the tremendous consumption of drugs and their consequent unexpectedly great cost, and it has impressed itself upon me that perhaps something useful might be said in consideration of the question of treatment by the use of drugs.

#### Treatment of Disease by Drugs.

To begin with it seems to be often assumed, or at any rate inferred, whenever the subject is dealt with in the press, that drugs in the treatment of diseases are in the main unnecessary and useless, and that when a doctor gives his patient medicine to drink, or a prescription to get it with, he is simply pandering to his patient's desire to get his cure that way, when he really does not want any medicine at all, but only requires advice. This is "the fetish of the bottle." I do not in the least agree that this is true as a generalization, though I am fully aware of cases in which it is true; and it cannot be denied that it is much easier and quicker to send off a patient with a prescription, which is all he thinks he wants, than to deal with him more faithfully with advice and instructions as well.

Again, there are among us those whose knowledge of drugs and their uses is, to say the least, elementary and limited to a very short list of common remedies—magnesium sulphate, sodium bicarbonate, rhubarb powder, opium, and perhaps sodium salicylate. These doctors have not taken much interest in drug treatment, and have not increased their repertoire by the useful methods of trial and error and experience. They tend to assume that treatment by medicines is largely a process of faith healing, and they are encouraged and comforted in this belief by the fact, thoroughly appreciated by us all, that the patient is cured by natural processes in himself, and that the cure is not accomplished by the doctor or his medicine. On the other hand, if one has been interested in trying out remedies, the occasions become very numerous when the patient's troubles can be greatly diminished and the course of his disease favourably modified by appropriate remedies, and I propose to relate here some of my own experiences. In these I do not claim to have any explanation, scientific or otherwise, for the actions or effects observed, but I claim the justification of experience.

In our beginnings and before we qualify we have to learn of drugs and their uses, and we have to know and be examined on the contents of that wonderful publication the *British Pharmacopoeia* (the revision and reproduction of which is under consideration now), full of remedies of greater or less potency for all sorts of conditions—many, I am convinced, of very small potency indeed, though widely

prescribed. Shall we take, for example, that popular bitter tonic gentian? The value of this is well illustrated by a story of the late Dr. E. Rickards, whose wisdom was well known to many of you. It was observed by one of his students that he frequently ordered an ammonia and gentian mixture, and in search of knowledge the student asked in what circumstances this medicine was prescribed. Dr. Rickards's reply was that he gave that mixture when he did not know what was the matter, when there was nothing the matter, when it did not matter. Other drugs there are of great and well recognized potency, but I have no intention to dwell on the uses of such as are known to be specific in the treatment of particular diseases—for example, quinine in malaria, mercury, iodide, and arsenic in syphilis, emetine in amoebic dysentery, salicylates in acute rheumatism, or opium in pain of different kinds.

#### Diminishing Use of Opium.

Perhaps the first observation I would make is the steadily diminishing use I find for opium. No! this is not the result of the Dangerous Drugs Act. So many kinds of pain are better relieved by other drugs, and even in the pain of incurable malignant disease, when we are in the end driven to it, I find that the morphine-relieved patient becomes so miserable and mentally altered, and requires so constantly increased a dose that I always experiment with combinations of other pain-relievers for as long as possible, in what I believe are the best interests of both the patient and his friends.

While speaking of cancer I am reminded that a man whose wife had been found to have inoperable carcinoma of the cervix uteri once came to me with an old copy of the *Lancet*, in which a doctor recommended trial of a formula which contained magnesium carbonate 5 grains, potassium citrate 5 grains, alum sulphate 2 grains, tincture of opium 2 minims, in cases of malignant disease, and asked if it might be tried for his wife. I of course consented, to find to my surprise that in a few days the pain was relieved and the haemorrhage and discharges steadily diminished, and for two years while she took the medicine her symptoms disappeared. She could not be persuaded to take it longer as she was satisfied she was cured. After leaving it off for a few months her symptoms returned and the medicine was this time powerless to stay the course of the disease. I have tried the formula since on many occasions, sometimes with apparently helpful results, but only in one other case, and that a pelvic growth, with anything like so surprising an effect.

#### Catarrhs: Aspirin.

Of the many and varied conditions with which the general practitioner has to deal I suppose it will be agreed that the catarrhs, acute and chronic, of all the various mucous membranes easily outnumber every other complaint, and perhaps there are no other illnesses in which the patient is more grateful for relief. The catarrhs of the respiratory passages are, I suppose, specially and peculiarly prevalent and persistent in our English winter climate. Take the common acute "cold in the nose" with its violent sneezing and profuse dripping—most uncomfortable and very depressing. We all know that it will pass through its various stages and disappear in due course, but the effect, upon many people in the pouring stage, of a few doses of ammonium chloride 10 grains, sodium salicylate 10 grains, chlorodyne 10 minims, is almost magical, but if the formula is taken to pieces and each constituent tried separately the same effect cannot be obtained. And when a catarrh has become bronchial and tends to stick I find that I usually turn to creosote and am rarely disappointed in the result. In combination with potassium iodide this remedy will often benefit cases of chronic bronchitis enormously. I have tried these two drugs in the treatment of acute pneumonia, but without any satisfying results. In the management and treatment of acute pneumonia I suppose that in the course of time we all evolve some general plan, and I am personally persuaded of two things: first, that it is dangerous or even fatal to give saline aperients, especially magnesium sulphate; and second, that expectorants are almost equally undesirable,

as they promote the flow of mucus and increase the risk of the condition which all must have seen where the patient literally "drowns" in his own bronchial secretion. Hence I usually prescribe, in the early stages, quinine and calcium chloride, hoping to keep the air passages dry, with the addition of opium when there is much pleuritic pain. And I expect it is fairly common knowledge that paraldehyde is often most effective with the sleepless pneumonia patient, and especially useful when nearing the crisis.

In the course of time and many epidemics every practitioner's procedure in dealing with influenza tends to stereotype itself. Curiously, I find in conversation with others that we all use different drugs, which would go to show that many are equally useful or useless, but after trying out all sorts of remedies I find that I get earlier relief of symptoms by the administration of quinine and aspirin (and here again neither is as effective by itself) than from any other remedies. The late Sir John Simon taught his students thirty years ago to give quinine and phenacetin, but I now prefer aspirin.

Of the many and varied uses of aspirin in pains and febrile conditions I do not propose to speak—they must be well known; but when thinking of its effects I always recall a case that surprised me. That is the worst of having no scientific explanation of a result. Another doctor once handed over to my care a chronic alcoholic of long standing with advanced cirrhosis of the liver and ascites. He was well off, and required to be tapped at regular intervals. On one occasion this patient complained of rheumatic pain in his shoulder-joint, and I ordered him some aspirin, to find that not only was his shoulder relieved but a diuresis commenced which so completely relieved his ascites that he never required to be tapped again, although his habits had not altered. A few doses of aspirin would always take it down if it showed any sign of return. This case of ascites is again associated in my memory with another of entirely different origin. A girl with advanced pulmonary tuberculosis had been away to a sanatorium at St. Leonards and made a surprisingly good recovery, but some time after her return home began to complain of indigestion and abdominal discomfort. Examination showed considerable free fluid in the abdominal cavity, and a diagnosis of tuberculous peritonitis was made. Treatment by rest and mercurial inunction produced no improvement, but administration of salol acted like a charm; the fluid and symptoms disappeared, and the patient has remained in good health for the last fifteen or more years. I can only record the observation without explaining the result.

#### *Intestinal Antiseptics: Nerve Sedatives.*

We are told that the intestinal antiseptics, so called, do not act as antiseptics to any appreciable extent, and I agree that it does not seem reasonable that they should; but of the usefulness of many of them in the treatment of intestinal conditions I am perfectly satisfied. Salol in conditions of catarrh or diarrhoea, alike in small children and older people, has come to be one of my sheet-anchors. In cases of gastric catarrh with furred tongue I find that the addition of half a minim of liquid carbolic acid to the ordinary dose of rhubarb and soda mixture often greatly increases its effectiveness. And again, where this is not effective two or three minims of tincture of iodine will often be helpful. In the treatment of mucous colitis, besides the use of salol to which I have referred, many will be aware of a formula advocated with great enthusiasm by Dr. Stacey Wilson: liquid perchloride of iron, liquid perchloride of mercury, and tincture of hyoscyamus, of each 15 minims, given half an hour before food. In some cases I have had excellent results with this, but not all patients respond either to this or to salol, and I have then found great benefit in some very severe and prolonged cases from iron and ammonium citrate 5 grains, liquor hamamelidis 15 minims, tincture of opium 2 minims, the opium being omitted where pain and diarrhoea are not present. Here again I have taken the formula to pieces and used the bits without getting the results. As a matter of fact I am particularly pleased with the use of this prescription, for it has enabled several chronic and miserable invalids to go to work regularly, and if they occasionally relapse, "the

bottle" (as the Scots patient has it) sets them on their feet again.

In these days, when it is so usual, or so fashionable, to suffer from "nerves," it often becomes a problem to know how to help nervy, jumpy, badly sleeping individuals. Bromide is capable of quieting them and helping them to sleep, but is liable to depress them further and may make them dependent on its continued administration. It occurred to me, as it doubtless has to many others, to try adding to the bromide some nux vomica or strychnine. Incompatible, some will doubtless say; they will cancel one another out; but experience has shown that potassium bromide 10 grains with liquor strychninae 3 minims is most helpful to the type of patient I have in mind. Bromide by itself depresses them; strychnine by itself is deadly for them—they become more jumpy and strung up at once. But the two given together produce calmness without depression, and help them to get back their sleep.

Another use of bromide I have in mind is in the vomiting of pregnancy, which I was taught as a student to treat with stomach sedatives—soda and bismuth—a method I found most disappointing until bromide was added to it. Bromide, perhaps with liquor sedans (P. D. and Co.) I have always found most effective in the vomiting of pregnancy. Again, all will be familiar with the indigestion of the tired and harassed business man which is immediately relieved by a dose of 10 grains of potassium bromide half an hour before a meal.

To-day the doctor is constantly being offered new remedies that require to be administered hypodermically—a horrible and increasing bugbear to the doctor, though I believe the modern patient expects and likes it. In the treatment of failing heart muscle the administration of adrenaline is recommended, and we are told that it is only effective when given hypodermically; but I have found that some good result is obtained when given by the mouth, and I have two cases of mitral disease with failing heart muscle in whom the benefit of digitalis is definitely improved by the addition of adrenaline, so that they, as well as I, can tell at once when it is omitted.

#### *The National Insurance Drug Bill.*

At the beginning of my address I referred to the great size of the National Health Insurance drug bill, and it would not be inappropriate if I made a reference to cost and economy. It is fortunately a fact that many effective remedies are not expensive, and I find that, by using inexpensive drugs when I can, I am able to order the most costly when I want them without exceeding a reasonable average price. To enumerate a few economies: Tincture of iodine, 5 minims in water, is a cheap and effective method of giving iodine in many cases. I so order it in arthritis, adenitis, and thyroid cases, though I do not find it effective as a substitute for potassium iodide in bronchitis or syphilis. Strychnine hydrochloride with chloroform or peppermint is an excellent tonic where indicated, as also is Easton's syrup, 30 minims in water. A very useful prescribing discovery was that aspirin is soluble in a solution of potassium citrate, so that it is possible to give these in a mixture and save a separate dispensing fee for tablets or the necessity of suspending the undissolved aspirin.

In concluding what I have described as a dip in a general practitioner's tool-kit I feel that apology is needed for presenting so fragmentary a discourse as a presidential address, but when I came to put my experiences together I was not able to find any consecutive scheme or plan on which to hang them. At the same time, I do feel that the publication of their experiences of the effects of the drugs in common use by those who see most of their results—the general practitioners—ought to be both interesting and useful.

I should like to make one further remark, and that is, that in presenting this one aspect of medical treatment I do not wish it to be thought that I am unmindful of the other and frequently more important factors in treatment, but if there are any here who are satisfied that the effects of drugs are mostly psychological, and that a placebo is generally all that is required, then I can only say—that I do not agree, and that such is not my experience.

1924

# INSTINCT AND FUNCTIONING IN HEALTH AND DISEASE.

DELIVERED TO THE ANNUAL MEETING OF THE YORKSHIRE BRANCH BY

PETER MACDONALD, M.D.,  
PRESIDENT OF THE BRANCH.

I HAVE within recent years been profoundly impressed by a new vista which seems to me to have been opened up by the work and writings of a layman—F. Matthias Alexander—with definite bearings upon the science and art of medicine. As Alexander's activities are almost unknown to the profession, although an appreciative review of his book, *Constructive Conscious Control of the Individual*, appeared in the *British Medical Journal* of May 24th, 1924, and as I have come to the conclusion that there is a *prima facie* case that his work is of first-class importance, and as if this be so, investigation by the medical profession is imperative, I decided to make use of this occasion to attract the attention of some members of the profession to it, in the hope that some person or persons better qualified than I am to make such investigations may have their interest aroused.

Perhaps I can start best by telling you how Alexander began his own investigations. He is an Australian, and as a young man was a reciter, and had in Australia a great reputation as such, and as a Shakespearian actor. He lost his voice, having contracted what is sometimes called "clergyman's sore throat," presumably a chronic or sub-acute laryngitis. He did what any other man in like circumstances would have done—he consulted a laryngologist. The laryngologist did what any other laryngologist would have done—he sprayed his throat and gave him inhalations, and prescribed rest, etc.—and the throat recovered. Alexander, accordingly, gave another recital, but by the end of it his voice had again failed. He went back to the laryngologist, who was also a friend, and advised another course of the same treatment which had been successful before. Alexander said "No"; the laryngologist asked "Why?"—and I beg you to note the answer. That answer was: "Do you not see? I went into that room with my throat right, and I was unable to recite. What caused the change from right to wrong? Do you not see? It must have been something I did. I will find out what it was that I had been doing wrong. When I have found out that I will cease to do it. When I have ceased to do it I will get my throat right, and I shall need neither your help nor that of anyone else." Then followed months of patient research. Mainly in front of the looking-glass Alexander made observations of how he used his mechanism—not only how he conducted himself in using his voice, but how he conducted himself generally; how he used that mechanism to sit down on a chair, how he used that mechanism to get up out of a chair, how he used it to walk, how he used it to kneel; how he used it to stand up straight, to bend, to kneel; how, generally, he used himself in the ordinary activities of life.

You will note the use of the looking-glass. Why was this? It was because Alexander had then—although but vaguely—recognized that in man's evolution from the stable environment in which he had passed by far the longest period of his life to the recent rapidly changing environment of what we call civilization, his sensory appreciation (that is to say, the knowledge which he derives from his feelings of what he is doing) is unreliable; so that, for instance, when he thinks he is standing up straight; that is, lengthening his spine—he is often shortening it; when he thinks he is relaxing muscles he is often tensing them; when he thinks he is putting his head forward he is often putting it back—a vague recognition which, his researches on himself, and subsequently on others, confirmed.

## INSTINCT AND FUNCTIONING.

From these researches certain conclusions were arrived at, the following being the most important:

(1) The first conclusion is that which I have indicated above—namely, that man's sensory appreciation is generally unreliable, particularly as regards knowledge acquired through the muscular sense. If Bain is right in his theory—that of all our senses the muscular sense is the most important—that, for instance, we derive our ideas of space and time; that, for example, I do not see that the wall at the other end of the room is about twice as far away as the chair near the middle of the room, but that I acquire that knowledge largely by the different amount of muscular energy I have to expend in turning my eyes so that they converge on a spot on the wall, and from expended when they converge on a spot on the chair, and from the different amount of similar energy I have to expend to focus each eye so that I can have a clear image of the wall in one case and of the chair in the other; and if it be further true that our sensory appreciation is unreliable, and that knowledge obtained through this sense is likewise unreliable, then civilized man is in a danger zone which will inevitably expose him to serious risks.

(2) The second conclusion is that, generally speaking, in the ordinary activities of life man uses himself badly: that he does not know how to get up to the best advantage from a sitting to a standing position, nor how to stand up when he is standing, nor how to get down to sit down when he is down, nor how to walk to the best advantage, still less to run to the best advantage, or to inspire and expire to the best advantage. Now, though the importance of the proper performance of these several functions varies in degree, you will agree that some of these activities, or others cognate to them, are associated with everything man does—whether he is presiding at a meeting such as this, or leading a parliament, or writing a book, or teaching the young, or ploughing a field, or leading a strike, making a motor car, or writing a play, or building a ship, or If Alexander is right, then, generally speaking, throughout his varied activities civilized man fails to function to the best advantage.

(3) Man is a psycho-physical whole, and does not consist of mind and body, or of head and trunk and legs and lungs and heart and liver; he is a unified whole, and if a part seems to be defective the defect is probably one of the whole mechanism, and not of the part. Take, for instance, flat-foot. This is not a defect of the foot alone, the remedy for which is something dealing with the foot alone; it is the result of a defect in the use of the mechanism which controls the carriage of the whole body, and may be got rid of by the means which will rectify this faulty use.

(4) Diseases are inseparable from wrong functioning, and in most of these wrong functioning is primary and disease secondary. Much disease can be prevented by the prevention of wrong functioning, and can be eliminated by the restoration of right functioning.

(5) Man differs from the lower animals in that in their conduct instinct is the important guide, and reason plays a small part; in man's conduct instinct plays a smaller and reason a greater part. Instinct is the result of accumulated racial experiences. Man, in the process of leaving the tree and arriving in this twentieth century in London or York, has taken, say, a million years. For by far the largest part of that time he has been in a state of savagery, or pre-civilization, less than 990,000 years; for by far the smallest part he has been in a state of civilization. Instinct, accordingly, is more than 990,000 parts due to the experiences of the civilization of the present day. Instinct, therefore, can be a sound guide to present conduct only if our experiences are similar to those of our ancestors. The experiences of our savage ancestors were acquired in a highly stable environment. Ours is a changing environment, and ever more rapidly changing; hence instinct has become, and is ever more and more becoming, an unsound guide to conduct, and it is ever becoming more and more imperative that for it should be substituted a conscious control.

These are among the more important of Alexander's conclusions, and it is not my purpose to-day to attempt to prove them, or to claim that they are all of equal originality or importance. My object is solely to attract attention so that others may be interested to investigate; but I would like to refer specially to the second and fifth of these conclusions.

The second is that, generally speaking, man uses himself badly in the ordinary activities of life. I would ask you to make some observations on your friends who are over 50 years of age, or still more over 60, and I am prepared

to wager that you will find that many of them have a waist measurement as large as, or larger than, their chest measurement, and you will find few in whom there is not present a stoop, with the chin thrown forward and head drawn back, with, if you try to move the head, an accompanying rigidity of the muscles of the head and neck, so that you will find difficulty in pushing the head on one side if you want to examine the ear. As I once before said in one of the Sections at an Annual Meeting of the Association, I do not believe that these manifestations are a result of old age; I believe that the misuse of the organism which brings them about constitutes one of the causes of it. Unfortunately, you find them in young people also, and, I think, increasingly so.

The second of the conclusions I wish to refer to is No. 5, and I will give two instances of how change of environment has converted a useful instinct into a harmful one, the second instance throwing some light, in my opinion, on why instinct, derived as it is from racial experience, tends to lessen health and promote disease.

(a) There is reason to believe that with primitive man, as is the case with many animals, the stranger was an enemy and was killed. This was generally an entirely reasonable process, and was arrived at from observations of experiences that if you did not kill him he killed you; or, where food supply was short, if he obtained the food you had to go without, and accordingly died. Though as regards persons this instinct has largely died out, and we now recognize that an advantage to one person does not necessarily or usually involve disadvantage to others, traces are left. *Hostis* is a Latin word with two meanings—the one is "stranger" and the other is "enemy"; and there used to be a tradition that there were villages where the normal thing to do to a stranger was to leave half a brick at him. But where the horde psychology comes into play, this instinct still continues, and there are persons who still believe that one nation's advantage means the disadvantage of other nations, and we still have hostile action in various spheres between nation and nation or class and class.

(b) My second instance, however, is one with an important relation to the science and art of medicine. I have come to learn from Alexander that health is associated with a satisfactory use of the mechanism which controls the carriage of the body, and that this control should be such that the spinal column is maintained as erect as possible. In other words, the vertebrae should be pulled away from one another rather than pressed together through a co-ordinated use of the mechanism which tends to elongate rather than depress. More particularly the control of the neuromuscular mechanism should be such that the neck portion of the spinal column should be continued up as straight as possible, with the head square on top of it, throughout most of the activities of life. These words "straight" and "square" are used for the moment loosely, and I am aware that they need further definition, or, probably better, demonstration, as I shall indicate later in this paper.

Those of you who know the work of Professor Magnus of Utrecht, and who have read the most important lecture he delivered at Edinburgh on May 19th and 20th on the physiology of posture, in which, for instance, he points out that in his experiments on "attitudinal reflexes" "the whole mechanism of the body acts in such a way that the head leads and the body follows," will see how the conclusion of Alexander as to the importance of the relation between head and neck, neck and trunk, is borne out by laboratory experiments. In fact, Alexander has in his work and in the technique he has devised for re-educating his pupils anticipated some of the results which Magnus and others have arrived at through these laboratory experiments.

If the use of the mechanism concerned with the control of the carriage of the body is thus satisfactory, the tension of the great abdominal muscles will not permit of the pendulous abdomen so often associated with age, with all its liability to visceroptosis and intestinal stasis.

Why is it the case that this right use and satisfactory carriage of the human body is rare? In my opinion it is due to the carrying over of a primitive instinct, which was once sound and helpful enough, into an environment where it has become unsound and harmful. The dominant factor of life in primitive man and the ancestors of primitive man must have been fear, and it is my belief that when man became *Homo sapiens* he dared not stand erect. If he

raised himself erect he was liable to be seen over the shrubs or grass in which he stood by sabre-toothed tiger or wood wolf or cave bear, and accordingly eaten. Hence he learnt to crouch and peer with head thrown backwards and down. It was a habit for which there was then a sound reason. But this instinct was carried over to civilization, where, instead of being an advantage, it has become a disadvantage in the sedentary environment of modern life, with resulting flaccid muscles, pendulous belly, and accompanying conditions. This is surmise; but let me remind you of the reason given why a horse, when it gets up, rises on its fore feet and then on the hind, whereas the cow gets up first on the hind feet and then on the fore. The reason given is that in the environment of fear—which is the common ancestral environment of all animals, man included—the horse raised his head up before his body because he lived on grassy plains; and he raised his head above the grass to look over it for enemies before he showed himself fully; whereas the cow lived in the forest and kept its head low to the last so as to look for its enemies below the branches where it could see them best.

It is an accepted scientific opinion that at the present stage of the evolutionary process modern civilized man is in imperfect adjustment to his environment. The importance of Alexander's work lies in his emphasizing the reality of this maladjustment of man's neuromuscular system, and in his having devised a technique for teaching pupils a right, or rather a better, use of themselves.

I cannot tell you much of the technique, for in the first place there is to-day no time, in the second I am not competent to do so, and in the third I am sceptical if it can be described in words. Words give such messages only from one brain to another as can be conveyed through the sense of hearing. Even the written word carries messages through the sense of hearing translated from the sense of sight. Words cannot be used to convey any meaning as to a sensory appreciation. You cannot really describe a colour in words so as to convey any meaning to another person unless he already knows the colour. Part of the technique, however, consists in the inhibition of wrong use. This is seldom easy, at least with adults. You all know how difficult it is to "keep the head down" at golf.

Another part is concerned with the method by which ends are attained. "Ends," says Alexander, "should not be arrived at direct." If the end is held in view successful attainment of the end is unlikely. Success is attained only by attention to the "means whereby" that end can be reached. With correct attention to the "means whereby" success in attaining the end is assured.

Let us again take a golf instance. I presume that there are few of you who have not had advice from a professional to "follow through" in driving a golf ball; and I am certain that no one of you ever met a professional who was able to tell you how to do it. In this, obviously, end-gaining gains no end; it only interferes with the attainment of the end desired.

If Alexander is right, then, the sound use of the mechanism and the elimination of instinct as a guide to that use is of first-class importance to all man's activities, and—what is of interest to us as a body of medical men—in the prevention of disease; and if it is as important as he says it is, his work should be incorporated in the education of our young, if only as a matter of preventive medicine.

Alexander is a teacher pure and simple. He does not profess to treat disease at all. If the manifestations of disease disappear in the process of education, well and good; if not, the education of itself will have been worth while. Manifestations of disease, however, do disappear. Including myself, I know many of his pupils, some of them, like myself, medical men. I investigated some of these cases, and I am talking about what I know. For instance, there was a case of flat-foot. Please note that Alexander was not directly interested in this foot. What he did was to teach the pupil how to use his brain and muscular mechanism in sitting down and getting up, how to comport his head in relation to his neck, his neck in relation to his thorax, his thorax in relation to his breathing, how generally to control the carriage of his body; and, in the process, not only the disabilities associ-

bed with dropped arches of the foot disappeared, but the dropped arches rose.

In other cases, under the like process, there seemed to be a distinct betterment in cases of angina pectoris, of asthma, of epilepsy, of tremor, of spinal curvature, and of difficulty of walking from locomotor ataxy, and from infantile paralysis. In short, I have seen, during the application of an educative process not directed to cure of disease, the manifestations of disease disappear, so that I personally am convinced that Alexander is at least largely right when he says that disease is the result of wrong functioning. And further, I am beginning to wonder whether there are manifestations of any form of chronic disease which may not disappear under a process of re-education on these lines, and whether McDonagh may not be right when he states in his great book that all disease is one; and whether the origin of that one disease does not lie in wrong functioning, and its different manifestations depend on different variations in functioning.

In conclusion, let me remind you again of my object in speaking to you. It is not, primarily, to communicate knowledge to you, but to endeavour to arrest the attention of some members of the medical profession to what I consider to be a most important development in connexion with medicine. I am in hope that I have made out a *prima-facie* case for investigation by competent observers.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### FOETAL TUMOUR OBSTRUCTING DELIVERY.

The following instance of what I assume to be a very rare complication of labour seems to be of sufficient interest to be placed on record.

A primipara, aged 27, commenced labour on November 20th at 4 p.m., being attended by a midwife. On the evening of November 21st the head of a full-time male child was delivered (left occipito-anterior), and as after many strong pains the body was not delivered, the midwife, at 8.30 p.m., sent for a doctor, and then the latter sent for an anaesthetist.

Examination showed an enormous tumour in the abdomen of the infant, making delivery impossible. Thinking this might be ascitic fluid the finger was introduced into the abdomen, but only a rubber-like mass was felt amongst the intestines. Finding it impossible to deliver the foetus, the doctor sent the case to the Kettering General Hospital. On examination in the lithotomy position the only possible thing—to deliver the head and arms, which were hanging outside the vulva, were amputated, the stumps disinfected, and the body of the child delivered in the usual way through the uterine wall.

The tumour proved to be a very large horse-shoe polycystic kidney with two distended ureters attached; it was twice as big as the foetus, and occupied the whole of the abdomen. There was no other kidney, and both suprarenal bodies were found. There were a very large number of cysts varying in size.

On November 22th the patient was making good progress, with normal temperature. Two days later, however, she had a severe haematemesis followed by copious melaena; the haemorrhage continued in spite of treatment and she died on December 3rd.

At the post-mortem examination four duodenal ulcers were found, one adherent to the liver, and another, a large one, attached to the pancreas. The haemorrhage which caused her death came from a large vessel in the ulcer adherent to the pancreas.

LESLIE W. DRYLAND,

Honorary Surgeon, Kettering General Hospital.

#### RESUSCITATION BY INTRACARDIAC INJECTION OF ADRENALINE.

Intravenous injection of solution of adrenaline chloride in cases of collapse at operation is known to have given satisfactory results. In the case here reported the intracardiac route was used, in a patient apparently moribund, with most dramatic and satisfactory results.

A man, aged 63, was admitted to Greenbank Hospital with strangulated right inguinal hernia. It had been strangulated three years previously and relieved by operation. The patient was in poor condition with bronchial signs and a bad pulse and albuminuria. It was decided to operate under intraspinal stavaine anaesthesia, preceded by a hypodermic injection of morphine and

atropine. He was placed in the recumbent position, and before the operation was begun seemed more listless and drowsy than customary, and the pulse was feeble. A hypodermic injection of 1 c.cm. of pituitary extract did not improve matters, nor brandy by the mouth. The pulse was absent at the wrist, he had Cheyne-Stokes breathing, and auscultation of the heart revealed no audible cardiac sounds. The patient seemed to have passed rapidly into a moribund condition.

Intracardiac injection of 10 minims of 1 in 1,000 solution of adrenaline chloride was ordered, the injection being given in the fourth interspace. The effect was magical. Before the needle could be withdrawn the heart was already beating vigorously, and the carotids were pulsating visibly. The patient then remarked that he was quite comfortable and felt no pain.

The operation was rapidly completed, attention being paid chiefly to relief of the strangulation, as the pulse began to fall away again after about twenty minutes. On returning to bed brandy and coffee were given by the rectum, and in a short time the pulse had again become normal. Apart from retention of urine the day following, nothing further of note occurred.

What the sudden collapse with Cheyne-Stokes breathing could have been caused by is not certain. Several possible explanations suggest themselves: (a) heart-block with Stokes-Adams syndrome; (b) drop in arterial pressure from spinal injection; (c) action of morphine on impaired kidney, causing uraemic manifestations; (d) gravitation of anaesthetic to medullary centres in spite of the rigid technique observed.

The rapid response to adrenaline suggests some profound vagal inhibition or heart-block with Stokes-Adams syndrome as being the probable explanation.

R. CHALMERS, M.D., F.R.C.S. Ed.,  
Honorary Assistant Surgeon, Greenbank Hospital,  
Dartlington.

#### TORSION OF THE MESO-APPENDIX ASSOCIATED WITH GANGRENE OF THE APPENDIX.

A complete twist of the meso-appendix is of some rarity; the following case is reported on this account.

A young adult male was admitted to the Royal Victoria Hospital, Belfast, suffering from abdominal pain. He had had no previous attacks of pain nor any previous illness. The attack came on in the night, two days before admission. It began with heavy crampy pains which awakened him from sleep. The pain was referred to the umbilicus. About noon on the following day he vomited and continued to vomit for some time. In the evening the pain eased somewhat and he slept at intervals through the night. On the following morning, however, the pain was worse; it had settled now in the right iliac fossa, and was so severe that he could not get up. It was constant during the day. At night it prevented him from sleeping, and at this stage affected him when he lifted the right leg. On the following day he was admitted to hospital. He was slightly flushed, the tongue was red and coated, and his breath malodorous. The right lower quadrant of the abdomen did not move freely on respiration. In this position a mass was to be felt, roughly the size of a hen's egg, lying beneath an area extending from McBurney's point to the lateral edge of the right rectus. It seemed to be lying directly beneath the anterior abdominal wall. There was no hyperaesthetic area. On rectal examination tenderness was found towards the right iliac fossa. His pulse was 94 and temperature 100.2° F. There was nothing to suggest that the case was of a type other than the usual one of acute appendicitis with a phlegmon.

At operation the appendix, surrounded by omentum, was found lying close up to the anterior abdominal wall. When the omentum was separated the appendix rotated itself in a clockwise direction through 180 degrees. It was then found that the mesentery of the appendix had still got a half-twist. The appendix itself, about 5 inches in length, was a necrotic mass from its tip to within a quarter of an inch of its base. It had not actually perforated, and considering its state there was less surrounding inflammation than is usually found. A drain of corrugated rubber, extending down to the ileo-caecal angle, was left for forty-eight hours. The wound was healed ten days later.

It is owing to the courtesy of Mr. S. T. Irwin, to whose ward the patient was admitted, that I have been able to publish this report.

The appendix in this case had rotated in an anticlockwise direction through a complete circle. This may have been secondary to inflammation with its resulting distension; but the fact that the omentum held the appendix rotated against its inclination shows that the appendix had become fixed to it when fully rotated. This suggests that the acute inflammation did not begin until the appendix was in the fully rotated position and that the torsion of the meso-appendix was the cause and not the result of the inflammation.

GEORGE D. F. McFADDEN, M.Ch. Belf.,  
F.R.C.S. Eng.,  
Assistant Surgeon, Ulster Hospital for Children.

## Reports of Societies.

### THE SENSE OF INFERIORITY.

On November 15th Dr. ALFRED ADLER of Vienna addressed the Royal Medico-Psychological Association on "The feeling of inferiority and its consequences." He said that every human being was continually striving to develop himself in some degree towards a self-satisfying completion, the full achievement of his life purpose. In every situation where the problems of living were being attacked there was to be observed this striving for superiority. A normal man had, in the main, three great problems to solve. First, there was the problem of social relationships, the desire to take some place in the world of men. The neurotic, in whom the degree of failure was usually very marked, must have another goal, and was always trying to escape from this normal aim of social life. The second problem was that of occupation, and the two were not wholly separated. Every occupation was a beginning of trying to be useful. To be useful induced a feeling of confidence and well-being. The third problem of life was sex. To unite with someone of the opposite sex was the normal goal for everybody. If the problem was being evaded there was a lack of self-confidence, a lack of courage, as in the case of neurotic subjects. The lack of courage might arise from an organic burden in childhood. To delicate children the world was a great difficulty, an embarrassing problem; and these burdens were remembered by them. The feeling of personal inferiority, in the case of children burdened with physical defects and deficiencies, was greatly intensified. Even the normal child suffered in a difficult situation, and if he had disturbances of vision or hearing, or some similar disability, he felt that he could not bear it. There were two situations peculiarly inimical to normal development. One of these arose where the child was made to face greater difficulties, in which case there was a greater feeling of inferiority. The other was concerned with the process of "spoiling." Such a child lived in a symbiotic manner, like a parasite, and received everything from others. He could not develop a normal style of life. The goal of children with organic deficiencies or of those who had been spoilt was to overcome the difficulties of life in the most complete fashion. For them there must be no less than the complete command of the situation, and their demands upon others were unlimited. Nervous patients often began as spoilt children. Such children were not capable of independence, of working with others for a common usefulness, and were always torn with conflicts. To a third type, the hated child, who grew up without warmth and love, was often illegitimate, or at any rate unwanted, the world was to a great extent comparable to an enemy country. Children of this type developed what might be termed a defensive attitude; they had no desire to join in with the efforts of others, and they had no wish to be useful in a hostile community. Thus they also were always in a situation of conflict. To accomplish their desire to be first in power and domination they restricted their environment, for they could not hold complete sway in the whole of society. They evaded occupation, and they evaded love; their eccentricities were always signs of evasion. Those signs of the attempt to escape the solution of the three questions of life were not always obvious, and it was rare to meet a man who frankly said, "I do not want to mix with others," or frankly avoided occupation. There were always justifications for evasions. Symptoms could be traced back often to childhood, and the history of the case invariably indicated such antecedent situations as had been considered in the three types of children. The spoilt child clung to the individual who spoilt him. Nervous people always attempted to justify the carrying out of their wishes to command other persons on the grounds of their anxiety. People who had agoraphobia required another person to be with them, and this other person must obey. If the neurotic person had a headache all the family must be silent, must obey, must take care not to irritate. This striving for superiority and for domination by any means developed in childhood. The symptoms could not be treated; they must treat the individual and change his

attitude to life. So long as the patient persisted in his morbid attitude one could not get rid of the symptoms.

Dr. Adler cited the case of a young woman, 26 years of age, in good bodily health, who had suffered for about a year with agoraphobia and depression. She dated the onset of her trouble a year previously, but the symptoms really originated in a change of her life situation when she had become a mother for the first time. She was a spoilt person, and aspired to be the centre of attention; the coming of a child of her own made her difficulty greater, and neurotic symptoms commenced. She often became very angry when her husband differed from her. They frequently quarrelled in spite of the love they had for each other. When the child came she felt that the time had come to reinforce her own position. The husband loved the child very much; she became more irritable and very depressed. She aimed at being the centre of attention, developed anxieties, and forced the husband to be with her always—an indication which explained her actions. She could not go on a tram and she could not travel by train, but she could drive in a car, since with a private car the stopping and the route could be controlled. In a sanatorium the patient improved considerably, but when she returned to her home she had a bad relapse. It appeared that in the sanatorium she found a physician whom she regarded as a very charming man; he flattered her and was always attentive to her. When she left she wrote him a letter full of kind thoughts, to which she had no reply, and from that time her symptoms increased. She built up a guilt-complex, concerning which she was very reticent; but it constituted an excellent tool for overcoming the husband. She said, "I could betray my husband, because he has left me, because he does not now flatter me as he used to, and is not so attentive to me." This breaking up of the marriage tie would have been an act of revenge against the partner. Though she was a very beautiful woman, she had lost her self-confidence. Her whole demeanour showed that she feared defeats and rebuffs. There was, in fact, a feeling of great inferiority. She could only dominate her husband through her agoraphobia and by means of her depression. The development of such an attitude to life, said Dr. Adler, could be prevented. The best course was to begin in childhood, to avoid spoiling the child, and not to overlook deficiencies in various organs. The aim should be to make the child independent, to make him free, to give him enough self-confidence and courage to develop his social feelings, to be useful, and not to be terrified by the other sex. If the patient had reached adult age he must be re-educated and given a fresh start. The attitude of the physician must be parental. The patients must be stirred to the depths of their personality; they required honest and frank handling, and no demands should be made upon them; one should simply seek to strengthen their courage, so that later they might feel independent.

[The full text of the lecture will appear in the January issue of the *Journal of Mental Science*.]

### ABNORMAL CANCER METASTASES FOLLOWING LEAD TREATMENT.

At the pathological meeting of the Liverpool Medical Institution, held on November 18th, Professor E. E. GLYNN read a short note on some remarkable histological changes occurring in the metastases of a case of carcinoma of the breast treated with colloidal lead.

Professor Glynn said that the patient had received two doses of lead, in all 0.175 gram, the last dose being given eleven days before death; there were no symptoms or signs of lead poisoning, and nothing exceptional beyond a terminal temperature and empyema. Metastases were present in the liver, lungs, suprarenals, and one enlarged gland. These metastases showed extraordinary stunting and deformity of the cells, which were depressed and flat; the nuclei were condensed, and did not stain well, the appearance being that of an autolysed sarcoma. There was also fatty infiltration of the liver. In the one enlarged gland, where the great bulk of it showed the same changes, there were also present perfectly healthy cancer cells, some of which were in mitosis. This was the only case noted in Liverpool that showed metastases in other organs and lymphatic

glands with these particular changes, which could be summarized as follows: Autolysis of cells, possibly due to lead, or an associated sepsis might have assisted. These changes could best be found within the first fortnight, and they were far in excess of what would have been expected from simple regressive malignant changes. Their extent depended upon a good blood supply, which was not present to a large degree in the case of a lymphatic gland.

#### Osteomyelitis.

Mr. R. KENNON read a note on osteomyelitis, and dealt with the acute condition first. Commencing immediately beneath the epiphyseal cartilage, an area sometimes termed the metaphysis, the primary focus was almost without exception within the cancellous bone; it spread in varying degree to the bone marrow, later to the periosteum, and finally invaded the intramuscular planes, subcutaneous tissues, and joints. The characteristic symptom being one-finger tenderness and pain over a bone end, it was aptly termed one-finger rheumatism of bone. The temperature was high and sleep was impossible. Swelling was a late sign, appearing with the tracking of the central abscess; pain and swelling were not synchronous as in rheumatism. Dr. Kennon then described the maximal points of tenderness in the upper and lower limbs, the posterior aspect of the lower end of the tibia above the epiphyseal line being the commonest site in the whole body. In explanation of these points of tenderness he showed pathological specimens illustrating the corresponding lesions, and also quoted various cases. The methods of spread of the subperiosteal abscesses from the various sites in the different bones were described, and also where they tended to point; the size of an acute subperiosteal abscess had no relation to that of the central abscess. The speaker compared this condition with tuberculous osteitis, and cited various authorities on the primary focus of infection. He said that if it was true that the lesion was primarily a bone lesion in the diaphysis, then it would mean that the distribution of acute infection and tuberculous osteomyelitis was the same. Mr. Kennon said that every practitioner ought to know where he would encounter the greatest pain and tenderness in a suspected case of osteomyelitis. Every radiologist should know on which bone surface the central abscess would burst, and arrange for multiple photographs accordingly. The surgeon should know these surfaces and drill them, so imitating Nature's method of bringing relief to bone tension. With regard to after-treatment, these osteomyelitis cases required as much open-air treatment as possible, just as in tuberculous cases.

#### Arthritis Deformans.

At the meeting of the Liverpool Medical Institution on November 25th Dr. H. S. PEMBERTON read a paper entitled "Arthritis deformans: observations on its etiology and treatment," an extension of a preliminary publication (JOURNAL, July 4th, 1925, p. 13) by Dr. L. S. Ashcroft, Dr. L. Cunningham, Mr. T. P. McMurray, and himself.

Dr. Pemberton dealt first with the difficulties of diagnosis from other forms of arthritis, and went on to outline the scope of their investigations into 64 cases. These cases had been studied from four aspects—clinical, bacteriological, metabolic, and therapeutic—the last being based entirely on conclusions drawn from the first three. On the clinical side he had little to say, beyond drawing attention to the relative infrequency of cardio-vascular changes, and commenting on the change of view which appeared to be taking place in regard to focal sepsis. On the metabolic side investigations into intestinal delay, acid-base ratio, renal and hepatic efficiency, basal metabolism, sulphur excretion, gastric secretion, and glucose tolerance were presented in some detail. Little or no change had been found in the rate of intestinal passage; no evidence of renal inefficiency had been found; the liver efficiency was doubtful as, although there had been no excess of urobilinuria, the blood-sulphur curves had indicated abnormality; the sulphur excretion was definitely increased; 65 per cent. of the fractional test meals had shown hypochlorhydria (50 per cent. of these being achlorhydria); and the glucose tolerance was impaired in practically every case. The basal metabolic rate had been found to vary very little. Illustrations were given comparing arthritic blood-glucose curves with those

of the normal diabetics, and the subjects of pancreatic disease, the latter being found to resemble most closely the curve in question. Slides were also shown of bone and joint changes in diabetes mellitus. On the therapeutic side the aim had been to make good or counteract the deficiencies which the investigation had shown to exist, such as deficient gastric secretion, diminished glucose tolerance, and increased sulphur loss. This had been done by giving as a routine (1) large quantities of 0.4 per cent. pure hydrochloric acid; (2) at first a carbohydrate-free diet of low caloric value, increased later by the addition of more fats, proteins, and some of the 5 per cent. carbohydrate foods; (3) colloidal sulphur; (4) massage first and then exercises. Comment was made upon the difficulties of a "carbohydrate-free" diet taken over a long period. The results were very encouraging in some 60 to 70 per cent. of the cases, and sometimes in as short a period as three weeks; it was felt that this therapy was of distinct value.

#### Recurring Acute Intussusception.

Mr. C. O. DAVIES, in a note on recurring acute intussusception, first described the case of a male infant, aged 5 months, who was operated on twice in the space of twelve weeks. On the first occasion an ileo-caecal intussusception was reduced, and on the second occasion the intussusception was of the ileo-colic variety. From a study of 32 cases reported in the literature the following conclusions were reached: (1) That recurrence of acute intussusceptions in childhood is rare, at the most amounting to somewhat less than 4 per cent. of cases. (2) The usual interval between the recurrences varies from two and a half to ten months; a few cases were met with where the interval was as long as two years. (3) There does not appear to be any necessity for trying to prevent recurrence, nor is there any reliable method of doing so. The importance of warning parents that a recurrence was possible, although not likely, was emphasized, and immediate re-operation urged as the treatment.

#### ACTION OF LOBELINE.

At a meeting of the Section of Therapeutics of the Royal Society of Medicine, held on December 14th, with the President, Dr. GEORGE GRAHAM, in the chair, Dr. S. WRIGHT read a communication by himself and Dr. F. R. CURTIS on the action of lobeline.

The authors began by recalling that lobeline was a pure crystalline compound obtained from *Lobelia inflata* (Indian tobacco) with the empirical formula  $C_{12}H_{16}O_2N$ . Since its isolation lobeline had been coming into clinical use, and they had therefore undertaken a reinvestigation of its pharmacology. Experiments had been carried out, in many cases decerebration having been performed to avoid the complicating factor of anaesthesia. Dr. Wright first described the experimental findings in the case of the heart. The initial effect appeared to be a slowing of the heart, the auricle particularly being affected, and this cardiac inhibition usually caused a fall in blood pressure. If the heart was in an enfeebled state this initial depression might arrest it altogether, but usually there was present a secondary effect, in which the heart rate returned to normal, and might accelerate still further. The effects on the heart appeared to be complex in character, consisting of initial stimulation both of the vagus nucleus in the medulla and the ganglion cells of the vagus in the nodes of the heart. These cells were later paralysed, and in addition lobeline had also a direct poisonous action on the heart muscle. The effect of lobeline on the blood pressure was then described. There was an initial fall, due probably to cardiac inhibition, followed by a marked rise, after which the blood pressure went back to normal, or, if larger doses were used, even below this. Lobeline appeared to act by first stimulating and then paralyzing the ganglia along the course of the vasomotor nerves. Coming next to the action of lobeline on the respiratory centre, Dr. Wright described how the drug markedly stimulates this centre, causing a considerable increase in the pulmonary ventilation. The doses required to produce such effects, however, also gave rise to the effects on the circulation already described. It appeared that the drug lowered the threshold of the respiratory centre to carbon dioxide, but it was possible

that the result might be due in part to constriction of the blood vessels of the medulla. The influence of lobeline was also studied in narcotized animals. In animals under ether anaesthesia pushed until the breathing had become slow and feeble, recovery was definitely more speedy if lobeline was used than in the control animals, allowed to recover unaided. In animals narcotized by morphine, lobeline increased the rate of respiration and led to adequate ventilation. If the respiratory centre was completely paralysed by morphine lobeline was much less effective, possibly because of the low blood pressure. Dr. Wright then reported the effects of lobeline on the bronchi, when slight constriction appeared to occur in some animals, and on other structures, describing how vomiting, micturition, and defaecation had occurred when large doses were employed. In summarizing, he stated that lobeline had been shown to be a powerful respiratory stimulant, but only in doses which produced other effects, and its use in patients with an enfeebled myocardium should be cautious. He suggested that it might be useful in cases of sudden respiratory failure from any cause, and would probably be more effective if combined with some cardiac stimulant. He suggested that a dose of 10 mg. intravenously would be found effective in the human subject, arguing from the dosage used in animal experiments.

Dr. J. H. BURN said that lobeline appeared to have the expected "nicotine" action, and suggested that adrenaline might be combined with it, the only objection being the necessity of giving the adrenaline intravenously. Pituitary would produce a more lasting effect on the blood pressure, or possibly lobeline might be combined with atropine to cut out the depressant effect on the heart.

Dr. PHILIP HAMILL pointed out that the disadvantage of lobeline was that its effects were not lasting.

Sir WILLIAM WILLCOX stated that he had used the drug several times, with beneficial results in one case of new growth in the chest associated with troublesome dyspnoea, and also in one case of persistent hiccup, where every other drug had failed. He pointed out that it had been used in coal-gas and morphine poisoning.

The PRESIDENT inquired about administration of lobeline to patients, and thought that it was of greatest use in cases of respiratory emergency.

#### Administration of Oxygen.

Dr. R. HILTON then read a paper on a comparison of some methods employed for administering oxygen. He pointed out that the primary aim in giving oxygen was to transfer this gas from the atmosphere to the blood, and accurate measurements of the result of this could only be carried out by arterial puncture. There were, however, two steps in this process—first, the oxygen is transferred from the atmosphere to the alveolar air, and secondly from the alveolar air to the blood. If the first step was successful the latter would probably run a parallel course, and hence his method had been to estimate the percentage of oxygen in the alveolar air in samples taken directly into the Haldane gas analysis apparatus. He dealt first with the traditional glass funnel held 10 cm. away from the face, and showed that in a normal person there was no effect at all on the percentage of oxygen in the alveolar air. If the funnel was held close to the face the results were better, the oxygen in the alveoli being nearly doubled, and with a shaped funnel held very close the results were only slightly better. With a nasal catheter with the end in the nasopharynx the results were even better; but Dr. Hilton remarked that a nasal catheter along which oxygen was passing at the rate of four litres a minute was not pleasant. The best results of all were obtained with breathing pure oxygen from a Douglas bag through a mask fitted with inspiratory and expiratory valves. In this case the oxygen in the alveolar air could be increased to 90 per cent. Dr. Hilton pointed out that many patients would not tolerate a mask and would pull out a nasal catheter, and he had recently been trying a mask which covered the mouth only. This appeared to be better tolerated, and it was possible to get alveolar air containing 50 to 60 per cent. of oxygen in normal persons by this method. He mentioned the great efficiency of a method

devised by Gilchrist and Davies for using a double-forked glass tube, placed in each nostril. He then discussed the ideal apparatus, mentioning the questions of cost, attention required, and the comfort of the patient. Although a mask over the whole face was most uncomfortable, the reasons for this were not quite clear. He stated that he had had no experience of the oxygen chamber. In his opinion the method of choice was a mask over the mouth, and he inquired if the oxygen pressure be raised to 60 per cent., was there any clinical advantage in raising it higher. He thought that arterial puncture and estimation of oxygen in the arterial blood was necessary to settle this.

The PRESIDENT thought Dr. Hilton's figures of great value, since oxygen as usually given in the wards was largely wasted. His own experience had been that a full mask was not well tolerated; he inquired if the mouth-mask was better for comfort than the nasal catheter.

Sir WILLIAM WILLCOX confirmed the uselessness of the glass funnel in his experience unless it was pressed over the mouth and nose. He hoped that a pleasant and efficacious method of giving oxygen would be devised.

Dr. P. HAMILL said that it appeared that a nasal catheter along which oxygen flowed at the rate of 1½ to 2 litres a minute doubled the oxygen in the alveolar air. He thought that better results would be obtained if the other nostril was plugged. Patients seemed particularly intolerant of any apparatus with an expiratory valve, and he asked about the use of a tube in the mouth.

Dr. DONOHUE HARE inquired about the nature of the mask used over the mouth.

Dr. HILTON, in reply, stated that the mouth-mask was a modified small anaesthetic mask inverted with its broad end uppermost, and that personally he greatly preferred this to a nasal catheter. He believed that a better effect could always be obtained with a nasal catheter if the other nostril was plugged.

#### SURGICAL ASPECTS OF DIATHERMY.

A discussion on the surgical aspects of diathermy took place at a combined meeting of the Sections of Electro-Therapeutics and Surgery of the Royal Society of Medicine on December 17th, when Dr. G. B. BATTEN was in the chair.

#### Various Techniques.

Dr. E. P. CUMBERBATCH, in opening, said that by the expression "surgical diathermy" European surgeons meant the passing through abnormal tissue of an electrical current of high frequency and of sufficient intensity to coagulate the tissue *in situ*. In the most common method a narrow disc electrode was applied to the tissue to be destroyed, and the completion of the circuit made by a broad plate electrode placed on another part of the body. When the current was started coagulation spread from the edges under the disc to the centre, and gradually extended below the surface. When sparks began to pass there was little or no further increase of coagulation. The coagulation in different layers of the tissue depth was in different degrees. Another method was to insert into the tissue a needle electrode. Coagulation began at the point of the needle and spread up the shaft to the surface, but before there was time for it to get to the surface the tissue in contact with the needle was desiccated. This method was much more under the control of the operator than the first. Coagulation would not spread more than 2 or 3 mm. from the point of the needle. A third method was that of circumvallation, a technique introduced by Howard Kelly of Baltimore. A single needle was used, and was directed from the surface obliquely downwards to a point under the abnormal tissue. Another method of using diathermy current for the treatment of malignant disease was a combined method of coagulation and cutting. In this method a narrow blade electrode was passed into the healthy tissue around the growth, the blade was slowly moved forwards, and the tissue cut. This was a difficult method, and it was very easy to move the blade too fast and get bleeding. Another method was fulguration, properly not diathermy at all, but a destruction of tissue by means of diathermy sparks, which bridged the gap between the point

electrode and the tissue to be destroyed. It was effective in the removal of moles and blemishes, and had been applied by American workers to the tonsillar region and in the destruction of haemorrhoids. Another method, that of electro-desiccation, was first employed in Philadelphia. Diathermic current of a low heating capacity was used, not sufficient to coagulate the tissue proteins. The reaction after desiccation of the tissue was very slight, and the cosmetic results were good. It could be used to destroy corneal ulcer, also for papillomata of the vocal cord. Finally, there were two methods of using high-frequency currents for cutting, in which the division of the tissues was effected by a minute electric arc. These procedures were called in Germany *lichtbogen Operationen*. A single needle was used, and when it came in contact with the tissues a little arc appeared, the needle was drawn across the tissue, which was divided with ease, and the capillaries and lymphatics were sealed as they were cut, so that the risk of producing metastasis when coagulating in the neighbourhood of malignant tissue was reduced. The tissues would heal by first intention after cutting. One of the methods was known as Wyeth's operation, used in America, in which a special current of enormously high frequency and sustained oscillation was employed. The other method was one which came to this country from Germany, via Sweden, and had been developed here by Mr. John Anderson of Dundee, in which again a special diathermic current in dividing the tissues produced surface cauterization, but over a rather deeper layer than in Wyeth's method. It was used largely in breast carcinoma. An exhibition was given through the epidiascope of both these methods in operation.

#### *Diathermy in Treatment of New Growths.*

Mr. F. J. STEWARD said that his own experience of diathermy was confined to the treatment of new growths, either malignant or pre-cancerous, situated on the surface of the body or within the mouth or pharynx. A comparison between diathermy and the cutting operation in the treatment of such cases would, he believed, establish the superiority of diathermy provided certain conditions of technique and choice of cases were observed. If the coagulation was carried well beyond the limits of the growth in all directions the result in respect to removal of tissue, separation of slough, and absorption was practically the same as after excision. Diathermy was practically a bloodless operation. In dealing with the mouth or fauces the danger from the inspiration of blood or septic material was practically eliminated. The general condition of the patient and his powers of resistance were conserved instead of being drawn upon by loss of blood. Post-operative shock was very slight. Freedom from loss of blood and diminution in the time of the operation no doubt explained the absence of shock in part, but it seemed likely that the trauma of coagulation was less severe than that of cutting. Convalescence was usually rapid and devoid of complications. The patient was comparatively free from pain, both immediately after the operation and during the process of healing. This acted as an inducement to use it as a palliative measure in hopeless cases. Finally, the rapidity of the healing and the character of the resulting cicatrix called for notice. In the operation certain requirements had to be observed. The destruction of the growth and of a considerable amount of healthy tissue surrounding it must be thoroughly and systematically carried out, and in order to accomplish this the growth and its surroundings must be fully exposed to view. A proportion of cases did not admit of satisfactory exposure, and on that account were unsuitable for diathermy. In order to avoid the possibility of missing any portion of the growth it was as well to mark out the limits of the area to be treated with a diathermy knife and then proceed to the systematic destruction of the tissue within the limiting line so drawn. He avoided diathermy when the growth involved bone. He had had only one satisfactory case where bone was involved—a case of large rodent ulcer of the frontal region. The possibilities of diathermy, he said in conclusion, would appear to be limited only by the need for satisfactory exposure of the growth and the general condition of the patient.

#### *General Discussion.*

Mr. GWYNNE WILLIAMS confined his remarks to the treatment by diathermy of cases of carcinoma in the mouth, which would be considered fit to be operated upon by the knife, and in which the diathermy knife was used as a substitute for cutting. Had it any advantage over the knife from either the immediate technical aspect or the ultimate condition of the patient? From the operative point of view there was less loss of blood, but vessels had to be tied, and there was a risk of reactionary haemorrhage. After the operation the patient had less local pain, and was generally less upset. If the mouth was kept rigorously cleansed there was no serious risk of secondary haemorrhage, but, on account of the depth of the slough, if sepsis did occur the danger was considerable. His impression was that the scar was softer after excision by diathermy than after the use of the knife. The ultimate result, so far as recurrence was concerned, was not affected, and would only be so theoretically if implantation of the growth on the raw surface at the time of operation was a factor in determining some of the recurrences.

Mr. DOUGLAS HARMER said that the first demonstration of surgical diathermy in this country was given at St. Bartholomew's Hospital by Professor Nagelschmidt, at the invitation of the late Dr. Lewis Jones, in 1910. Treatment of this kind was started at that hospital in the following year. One patient who was treated in 1911 for epithelioma at the corner of the eye remained well for twelve years, and then, on a certain amount of recurrence taking place, was treated with radium needles. She then remained well until a few days ago, when diathermy was again applied. He showed photographs of a number of other cases of fairly long standing, including one of rodent ulcer of the nose, in which the lower part of the nose was removed by the diathermy knife. The wound healed rapidly, a plastic operation was performed, and the patient had remained well and free from recurrence for three years. With regard to growths in the upper jaw, he thought there was no doubt that since diathermy had been employed the number of cures obtained had been almost doubled. The route that he preferred in these cases was through the palate. Such an exposure gave good access to most of the malignant growths in the upper jaw. In that way they were thoroughly burned with diathermy, and afterwards treated with radium, large doses being used for about forty-eight hours, and as a rule good results were obtained.

Mr. H. H. RAYNER spoke of his experience in the diathermic treatment of cancer of the skin and the palliative treatment of cancer of the breast. He believed strongly that the risk of local recurrence was diminished by the use of diathermy. In its use in cancer there were three types of cases in which it was advantageous: (1) in extensive rodent ulcer, in which radium had been used and had failed or in which radium was plainly inapplicable owing to the extent and connexions of the growth; (2) in advanced lupus epithelioma (cases in their early stage could be dealt with by ordinary surgical measures); (3) in that type of epithelioma which was extremely foul and heavily infected, and in which there was a risk of serious sepsis following any ordinary surgical operation. In palliative treatment of cancer of the breast in cases which were beyond question inoperable, he believed that diathermy could be of substantial benefit. Such patients might be enabled to live a fairly active life for one or two years.

Dr. THOMAS MARLIN said that in certain quarters there was a misconception as to the course of the diathermy current. People were accustomed to talk of diathermy as a penetrative current, the heat being generated between the electrodes, and had the idea that there was no diffusion of current. Some even believed that the current could pick out certain tissues and heat them to an unhealthy temperature. The speaker detailed certain experiments in which he had passed the current through meat, eggs, potatoes, and so forth, and showed that the current did spread a little, as distinct from heat diffusion; that at no point between the electrodes was it stronger than just under the small electrode; and that heat was not generated in one kind of tissue more than in another.

Mr. GORDON TAYLOR, from an experience of more than 100 cases of operable carcinoma of the mouth treated by diathermy, was convinced that the ultimate results of the treatment of carcinoma of the tongue by this method were better than those following the old method with the scissors or the knife. The only objection was the increased risk which these patients seemed to run of getting broncho-pneumonia. Of those who got over the operation 50 per cent. seemed to have a chance of freedom from the disease for at least six years. Secondary haemorrhage was said to be a risk incurred in connexion with diathermy. In 84 cases of carcinoma of the tongue he had had only two secondary haemorrhages, one of which was very slight and easily controlled; the other was from the lingual artery, and in that case also the patient got well. In inoperable malignant growths of the mouth there was no question that diathermy was a very useful means of helping these unfortunate individuals. He had also used diathermy in the treatment of inoperable carcinoma of the breast. For the last ten months he had had experience of the light-arc operation practised by Mr. Anderson in Dundee—a method which, he thought, came originally from Sweden. It seemed to him that this operation held out considerable advantages over the ordinary knife method.

Mr. JOHN EVERIDGE said that it was common knowledge that the diathermic cautery presented enormous advantages in papillomata of the bladder. Recurrence seemed to take place with a good deal of frequency after the use of the cautery, and that was not to be wondered at, because only the papillomata which could be seen were destroyed, and the tendency of the bladder to form papillomata was not overcome. Secondary haemorrhage occurred with considerable frequency; in fact, in the majority of cases there was a fair amount of bleeding about the end of the first week, but he had not yet met a case which caused great anxiety. The treatment of carcinoma of the bladder with the diathermic cautery was another story. The results in his hands had not been at all good. Indeed, when the diagnosis was somewhat doubtful, the response to the diathermic cautery would show whether the condition was one of carcinoma or otherwise. The diathermic cautery was useful also in prostatic enlargement, particularly where there was a projection into the prostatic urethra or the neck of the bladder. Reference had been made to the small amount of scar tissue after the use of the diathermic cautery, and in no part of the body was it more important to prevent the formation of scar tissue than at the neck of the bladder.

Mr. PHILIP TURNER said that his attention was first attracted to the value of high frequency in surgical conditions at the Surgical Congress in Paris in 1908, and on his return he and Dr. C. E. Iredell started to treat malignant growths by fulguration, and some excellent results were achieved in cases of rodent ulcer. With regard to the indications for diathermy, rodent ulcer certainly gave the best results, and the most suitable type of rodent ulcer was one that was too far advanced for excision or in which the anatomical situation made the prospect of excision not favourable. Carcinoma and epithelioma, especially of the tongue, fauces, the floor of the mouth, and the pharynx, were also suitable, and another indication was in cases of extensive breaking down of tuberculous glands of the neck. His own results corresponded with those already mentioned—absence of pain and shock, a healthy granulating surface, and a remarkably supple scar. He had been doing diathermy now for eighteen years, and he could recall very few accidents—three burns, one a bad one, four secondary haemorrhages, one from the lingual artery, and, finally, one explosion, due to some ether in the operating theatre. Generally speaking, he had found, as regards local conditions, that the results were satisfactory, but many of the patients, especially those treated for conditions in the mouth, died afterwards with recurrences in the neck. It occurred to him that it might be possible, by previous injection of colloidal copper for many days before the operation, to guide the diathermic needle along the lymphatic tract, the idea being that the colloidal copper would be taken up by the cells of the growth, and the current be guided in that way. What actually happened, he believed, was that the copper impaired the vitality of

the cells and so enabled the diathermy to act more effectively.

Dr. C. G. TEALL spoke of the treatment of growths of the oesophagus. He had applied diathermy in these conditions, feeling that from the patient's point of view anything was better than gastrostomy. By using a specially designed electrode which enabled one to restrict considerably the area to be burned, quite good results had been obtained of a palliative kind. One could burn away through the mouth, and yet be quite certain that the coagulation was being restricted to a very small area immediately around the electrode.

Dr. C. P. LANKESTER said that he had treated a few cases of haemorrhoids by diathermy, and had been greatly struck by the entire absence of pain afterwards. He regarded diathermy as by far the most satisfactory procedure in this condition.

Dr. CUMBERBATCH, in replying to the discussion, said that in the United States the use of the disc electrode—the first of the methods he had described—was now largely discarded, and the circumvallation method employed. He thought that no safe deductions could be made from experiments with potatoes and so forth. The problem of the distribution of the current in the living tissue was really very complicated, and the diffusion of heat, the frequency of the current, the mode of oscillation, and the type of conductor all played a part. The *lichtbögen Operation* was learned by Mr. Anderson in Forsell's clinic in Stockholm in 1923, but originally, he thought, it came from Germany.

Mr. STEWARD, also in reply, said that his pessimism with regard to treating cases by diathermy when bone was involved had been to some extent removed by certain cases shown that evening, and he was prepared to try again. To his mind the discussion demonstrated the great use of diathermy already in the field of surgery, and he believed that as a result of that discussion there would be still further advance.

### DIAGNOSIS OF CORONARY THROMBOSIS.

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland on December 3rd, with the President, Dr. G. E. NESBITT, in the chair, Dr. LEONARD ABRAHAMSON read a paper on the diagnosis of coronary thrombosis, in which he discussed the recent literature and the symptoms by which this condition could be recognized during life. He stated that clotting of even a large branch of the coronary system might be followed by recovery. The cause of the condition was apparently syphilis.

The PRESIDENT raised the question of the diagnosis of coronary arterio-sclerosis, which seemed to be a precursor of coronary thrombosis.

Dr. R. V. MURPHY mentioned a case he had recently seen. The patient was an old age pensioner, who when admitted to hospital was very ill and just recovering consciousness. He was cyanosed and very pale. He stated that he had had no previous illness, but had suddenly felt an agonizing pain over the pericardium. While consciousness was returning the pain was very severe; there was auricular fibrillation, and a ventricular rate of about 90. The heart sounds were weak, but there was no enlargement and no murmur. At first Dr. Murphy thought that it was a case of an acute abdomen, but after examination he concluded that the trouble was in the heart—either a thrombus or an embolus of the coronary artery. The patient recovered to a certain extent, but died within about forty hours of the attack. No necropsy was allowed.

Dr. C. J. MURPHY described the case of an elderly woman, who complained of pain coming on suddenly over the pericardium. Her pulse was feeble, and her blood pressure low; she had pyrexia. She suffered from vomiting, and the liver was enlarged, as was also the heart. She died very shortly after the onset of the attack, previous to which her blood pressure had been high. She had been treated by Erlangen rays for sarcoma of the maxilla, which had cleared up absolutely after treatment. The necropsy showed an aneurysm of the aorta ruptured into the pericardium.

Dr. ABRAHAMSON, in reply, said that it was not easy, in his opinion, to diagnose coronary arterio-sclerosis, but in America it was diagnosed by electro-cardiograms. It was

possible for a patient to have a narrow coronary artery for many years, without showing symptoms, and then suddenly to get a thrombosis.

#### Serum Treatment of Scarlet Fever.

Dr. J. H. POLLOCK read a paper entitled "Observations upon scarlatina." He dealt with the question of the frequency of *Streptococcus haemolyticus* infection as shown by blood cultures and metastatic abscess formation. He believed that a streptococcus septicaemia was very frequent.

The PRESIDENT remarked on the large numbers of cases in which Dr. Pollock had found streptococcus. He had used anti-scarlatina toxin to some extent at the Richmond Hospital, but it was expensive, and in his cases he could not say that it had had any remarkable effect, and was by no means comparable with the effect of diphtheria antitoxin. It was generally claimed that patients could be discharged from hospital in three weeks after the administration of antitoxin.

Dr. W. CHORTON drew attention to the fact that English investigators had for years persistently maintained that a streptococcus was the cause of scarlet fever, though the Americans got the credit for it.

Dr. W. E. HERMISTON said that he had been at Cork Street Hospital for a year while cases of scarlet fever were being treated on the ordinary lines; after that time serum had come in, and patients had been treated with it. He had no doubt whatsoever, from a comparison of the treatments, that anti-scarlatina serum was the best treatment for this disease. He mentioned one patient who on admission had been absolutely comatose; 10 c.cm. of serum was given that night, and 10 c.cm. the next morning, and an uninterrupted recovery followed. He could not be sure whether the giving of serum lessened the complications that arose in cases of scarlet fever.

Dr. R. J. ROWLETT asked if all the patients treated were cases of true scarlet fever, or of sepsis simulating this condition. It was important to make a distinction between cases of true scarlet fever and cases of acute sepsis with a rash. He asked if the use of vaccines made from the organisms which were separated from the blood had been tried. He thought that probably an autogenous vaccine would be more helpful than serum, and that vaccine and serum together would be more helpful than either alone.

Dr. POLLOCK, in reply, said that they had found at Cork Street Hospital that the giving of serum did not make any difference regarding the length of time of convalescence. As time went on, he thought it possible that scarlet fever would be regarded as a much less separate entity than it had been considered recently, and he also thought that the nomenclature of many of the fevers would be changed in the future.

#### Haematoporphyrinuria.

Dr. R. H. MICKS and Dr. W. R. FEARON described a case of haematoporphyrinuria. The urine was a deep port-wine colour, and showed no absorption bands. By adding 10 per cent. barium chloride solution drop by drop to boiling urine the pigment was carried down with the precipitate of barium salts, and removed from the precipitate by extraction with glacial acetic acid, or with a 5 per cent. solution of sulphuric acid in 90 per cent. alcohol.

Dr. R. R. LEEPER said that the patient from whom the urine was obtained was a man who had been under his care for some years, and suffered from dementia praecox; he was cyanosed in the extremities, as such cases often were. One night he had retention of urine; the urine was drawn off, and haematoporphyrinuria was found. The patient had had no drug treatment.

Dr. ABRAHAMSON thought that this case was of the acquired variety of haematoporphyrinuria, since the cause was not apparent. He referred to four cases of this condition which he had reported in the *Quarterly Journal of Medicine*, two of which were of the acquired type and two congenital.

Dr. A. R. PARSONS referred to a case of haematoporphyrinuria, a specimen of which he had shown at the Academy in 1906. The patient, a woman aged 23, complained of very severe abdominal pain, constipation, and sleeplessness, for which there was no apparent cause. The urine was generally normal when passed, but later changed colour

and became the colour of port wine. The patient had had no drug treatment. She recovered and left hospital, but about a month later she returned, being much worse. She developed symptoms of peripheral neuritis, and died some time later. Alkalis were freely given, but without any benefit.

#### Chronic Gastric Ulcer.

Dr. E. T. FREEMAN read notes on a case of chronic gastric ulcer, and showed radiograms illustrating its healing. The patient, aged 45, had had abdominal pain for seven years; this was worse in the summer and early autumn, when he was in the habit of eating much fruit. He complained of pain at the ensiform cartilage, especially when standing erect, and could not walk, stand, or sit up without discomfort. There was slight tenderness in the mid-line, no enlargement of the liver, and no tender or palpable gall bladder. He looked slightly jaundiced, and had bradycardia; the teeth were excellent, and there was no obvious infection of the tonsils. A fractional test meal showed hyperchlorhydria, and some leucocytes and blood cells. An x-ray examination showed an ulcer on the lesser curvature with a large crater towards the pancreas; there was slight pylorospasm, and duodenal irregularity. The ulcer was of the type for which surgical intervention was usually suggested, and for which gastro-enterostomy would be useless, as the pylorus emptied normally. The patient was put on a rigid Sippy diet—milk and cream every hour, with alkaline powder between, and tincture of belladonna each night. Eggs, ground rice, bread-and-butter, and vegetable purées were gradually added. At the end of three weeks he was allowed fish and was then taking three small meals daily, with milk, cream, and alkalis between. He had now been on an almost normal diet for some months, with alkaline powder and cream mixture. He was not allowed to eat a greater total quantity than twelve ounces at any meal. The patient had been free from symptoms since the second day of treatment; credit was due to him for his complete co-operation. The aphorism had been attributed to Sir J. K. Fowler that no fool was ever cured of pulmonary tuberculosis. Dr. Freeman suggested that the same was true for gastric ulcer.

Dr. R. H. MICKS referred to an article by Einhorn and Crolin of New York, in which were mentioned 101 cases of gastric ulcer treated medically during the last four years. They stated that about 80 per cent. were cured after a year, but that after four years, of the cases that had been treated, only about 50 per cent. had not relapsed. He thought that in the average working-class patient this was the most that could be hoped for.

#### JAMES MACKENZIE INSTITUTE.

On November 23rd Professor ADAM PATRICK read a paper on diabetic coma. He referred first to the known facts regarding the chemistry of ketosis, and showed how imperfect carbohydrate utilization might be the result either of deprivation of sugar or of inability to assimilate it. He emphasized the importance of aceto-acetic acid in the body, and said that there was no point in elaborating tests to distinguish this substance from acetone in the urine. Dealing next with the symptomatology of the condition, he laid stress on the early signs of impending coma, especially abdominal pain. He advised treating every symptom which appeared out of the ordinary as the possible commencement of coma. He contrasted the symptoms of coma with those of hypoglycaemia, and showed how in the latter the prominent symptoms were nervousness, mental excitement, tachycardia, and, it may be, diplopia. In regard to treatment, he pointed out the importance of making every effort to prevent the occurrence of coma by attention to the diet laid down, and especially by avoidance of any change which would cause difficulty in accurately adhering to the ordered regimen. In conclusion, Professor Patrick gave a detailed account of methods of treatment of coma once established, up to 200 units of insulin being given in the twenty-four hours, with control by two-hourly examination of specimens of urine. He mentioned the utility of the duodenal tube in facilitating the introduction of large quantities of fluid, as recommended by Poulton.

## Rebuelus.

## GRAY'S "ANATOMY."

THE appearance triennially of a new edition of Gray's "Anatomy" must now be regarded as an established tradition, and in keeping with it there appears this year the twenty-third edition. The nature of the subject matter and the fact that the book is mainly intended for students preclude much possibility of originality and expansion. The successive editions, however, give ample evidence of careful and exhaustive revision. Compared with that published in 1923 the present edition possesses twenty-two more pages and twenty-nine more illustrations. The increase in size is largely due to these illustrations, but important additions have been made to the text of those sections which deal with general anatomy, angiology, and the endocrine organs. Of the new illustrations those showing intramembranous ossification of bone, blood platelets, the dome of the pleura, the bed of the stomach, and the relations of the extra-hepatic bile passages are particularly valuable. While we are strongly of opinion that in such a textbook only observations of unquestioned accuracy should be included we are inclined to think that the editor's native caution might have been here and there slightly relaxed with advantage; for instance, reference might have been made to the palmar compartments described so well by Kanavel. Perhaps, too, a short note on the action of the palmaris brevis muscle recently described by T. S. Kirk might have been included. We should have liked also to find a less meagre account of the development of the vertebral artery, since it illustrates so admirably the arrangement in the embryo of the cervical segmental arteries. The only criticism we would offer on the illustrations is that in figure 107 the impression may, we fear, be conveyed that both the anterior and posterior tubercles of the transverse processes of cervical vertebrae are derived from the costal elements.

Such criticisms as these, however, are obviously of very small moment and should not in any way obscure the great outstanding merits of a work which is honourably known to many generations of English medical men—a work of which the last edition is indubitably the best.

## NEPHRITIS.

DR. HERMAN ELWYN, assistant visiting physician, Gouverneur Hospital, New York, has dedicated to Professor Franz Volhard a well written work on *Nephritis*,<sup>2</sup> which contains much evidence of his inspiration. The diseases known as Bright's disease or nephritis are treated in successive chapters, and the bibliography is conveniently indicated, but there is a lack of illustrations. The author adopts Volhard's classification into the three groups of glomerulo-nephritis, nephroses or tubular degenerative nephritis, and arterio-sclerotic diseases of the kidney. These main headings are subdivided: thus glomerulo-nephritis is either focal or diffuse, and the focal may be embolic or non-embolic; the diffuse may be acute, subacute, subchronic, or chronic. Under the heading of arterio-sclerotic diseases there are included (1) cases with arterio-sclerosis of the renal artery and its larger branches, which do not present any definite clinical picture, (2) cases of renal arteriolo-sclerosis without any evidence of renal insufficiency but presenting the clinical syndrome of benign hypertension, and (3) renal arteriolo-sclerosis with renal insufficiency, the malignant form of renal arteriolo-sclerosis, or the malignant form of hypertension. Among the early chapters are two dealing with uraemia and hypertension generally; later the benign and malignant forms of hypertension are considered under the heading of renal arteriolo-sclerosis, where the problem whether or not high blood pressure causes or is due to the renal arteriolo-sclerosis is discussed.

Much stress is laid on heredity as determining the characteristics of the arterial walls and of the vasomotor system.

The nephroses are well described in separate chapters dealing with the lipoid, the amyloid, and the mercurial forms. Lipoid nephrosis, first investigated clinically by Vollhard, does not show any impairment of function by functional tests, and the accompanying albuminuria is, after a full discussion, ascribed to a disturbance in the intracellular respiration of the glomerular and capsular epithelium, and possibly to an acid intoxication of the cells. The treatment of lipoid nephrosis is Epstein's high protein diet, restriction of fats, and administration of thyroïd, which was introduced by Eppinger before its justification by the low metabolic rate was known. In the account of amyloid nephrosis it is pointed out that oedema is mainly dependent on the addition of lipoid nephrosis, and that in the absence of this change oedema is either slight or does not occur at all. The special form of nephrosis due to mercury perchloride poisoning is fully discussed, and the necrosis of the renal epithelium is stated to be probably due to two factors—the direct action of the mercury and temporary cessation of the blood supply. The various views held about puerperal eclampsia and the kidney of pregnancy are stated before the author puts forward his suggestion, which would obviate the need for a hypothetical toxin—namely, that a greatly increased neuromuscular irritability causes spastic arterial contraction.

This is a clear presentation of the modern aspect of a subject which has undergone great changes during this century, and as such deserves a cordial welcome.

## PRACTICE OF PHARMACY.

*Remington's Practice of Pharmacy*<sup>3</sup> has been the standard American work on this subject since the appearance of the first edition in 1885. The seventh edition, which has just appeared, is a massive volume of more than 2,000 pages, which deals in an encyclopaedic manner with every subject that is of professional interest to the pharmacist. Professor Remington died in 1918, soon after the appearance of the sixth edition, and the present edition has been prepared by Professors Cook and LaWall, who assisted Professor Remington for many years in the editing of previous editions of this work.

The *Practice of Pharmacy* covers a remarkably wide range of subjects, and the editors have been assisted by the expert advice of no fewer than thirty-nine collaborators. The volume is divided into seventeen parts. The first six occupy half the book, and describe the technical operations in pharmacy and the substances used in pharmacy. The general form and arrangement have not been altered since the last edition, but its scope has been enlarged by the addition of certain chapters dealing with aspects of the pharmacist's work that are becoming of increasing importance in the United States. Such chapters are those on "The responsibility of the pharmacist under the law," "Scientific business methods and control," "The pharmacist as analyst," and a chapter on toxicology and antidotes.

An interesting feature of the introduction is the quotation in *extenso* of the principles of pharmaceutical ethics adopted by the national pharmaceutical organizations and the colleges of pharmacy. One important clause of this states that the pharmacist should as far as possible encourage the use of official drugs and preparations and discourage the use of objectionable nostrums, and this last term is defined by a statement of the minimum requirements with which a proprietary preparation should comply.

A noteworthy feature of the book is a chapter on biological products, which gives a clear account of the mode of preparation of antitoxins, vaccines, etc., the tests for potency, and the precautions needed for storing and dispensing such preparations.

About half the volume is devoted to the consideration of the drugs used in pharmacy, and a full account is given of the tests for purity, chemical characteristics, mode of preparation, and history of all the standard drugs; this

<sup>2</sup> *Remington's Practice of Pharmacy*. Seventh edition. By E. Fullerton Cook, P.D., Ph.M., and Charles H. LaWall, Ph.M., Pharm.D., Sc.D., F.R.S.A. London: J. B. Lippincott Company. 1926. (64 x 9, pp. xxiv + 2090; illustrated. 45s. net)

<sup>1</sup> *Anatomy, Descriptive and Applied*. By Henry Gray, F.R.S., F.R.C.S. Twenty-third edition, edited by Professor Robert Howden, M.A., M.D., C.M., D.Sc., LL.D. London: Longmans, Green and Co., Ltd. 1926. (Roy. 8vo, pp. xiv + 1400; 1,294 figures. 42s. net.)

<sup>3</sup> *Nephritis*. By Herman Elwyn, M.D. London: H. K. Lewis and Co., Ltd. 1926. (Univ. 8vo, pp. 373; 2 plates. 21s. net.)

portion of the book has been carefully revised, and the new edition fully maintains the reputation of the work as a standard encyclopaedia for pharmacy, and the editors have certainly done their utmost to provide full and up-to-date information for the pharmacist concerning every aspect of his multifold activities.

### BOOKS FOR NURSES.

Dr. F. A. ROUGET, who is in charge of the Civil Hospital in Mauritius, has been engaged in teaching nurses for the last twenty years. He has embodied his teaching in his *Précis de Nursing Médical et Chirurgical*,<sup>4</sup> which has reached a second edition. Dr. Rouget is of opinion that in training nurses it is necessary to guard against too low and too high a standard. A nurse should not be a mere machine; she must understand the why and wherefore of measures she is called upon to carry out. Initiative based on knowledge is of great value where the services of a medical practitioner are not easily available. So Dr. Rouget has made his book a theoretical and practical guide for the use of certificated nurses. As such it covers a vast amount of ground, but it is written in the rather unpleasant style of a compendium or synopsis which is so popular nowadays in works of this description. As a book of reference it might be more useful to the nurse if an alphabetical index were added to the table of contents.

A small *Outline of Surgical Nursing*<sup>5</sup> has been prepared by Dr. WOODALL in accordance with the syllabus of the General Nursing Council's examination in surgical nursing. More attention is given to classification of symptoms and treatment than to a description of appliances and tools, of which a nurse gains practical experience in the wards and theatre. The book is understandably written and brief, but stimulating allusions are occasionally made to the history of medical discoveries. After an account of inflammation and repair, there is a section on bacteriology and immunity, followed by a description of the diagnosis and treatment of haemorrhage, fractures and dislocations, burns, and ulcers. The requirements of the modern operating theatre are stated, as is the way in which a private house should be prepared for an operation. Due importance is assigned to post-operative nursing, and particular points about individual operations are mentioned. A chapter is devoted to the treatment and nursing of venereal disease, and another to gynaecology. The book will help a nurse who wishes to be proficient in surgical nursing.

*The Theory and Practice of Nursing*,<sup>6</sup> by Miss M. A. GULLAN, sister tutor of St. Thomas's Hospital, has also reached its second edition. The book summarizes the instruction given to nurses training in the Nightingale School of St. Thomas's Hospital. Miss Gullan says that her book is suggestive rather than exhaustive. She does not set out with the idea of teaching a nurse all she ought to know. She confines herself rather to matters which are directly connected with nursing; and, in order that the nurse may record the increase of her knowledge, blank leaves for notes are attached to each chapter. The book is clearly written, very well printed, and should be extremely useful to nurses.

The appearance of the seventh edition of Dr. J. K. WATSON's *Handbook for Nurses*,<sup>7</sup> of which the first was published in 1899 and the sixth in 1921, is testimony of its appreciation by many generations of nurses. The principal features of the present edition are an expansion of the chapter on digestion, dietetics, and artificial feeding,

and a description of recent work on scarlet fever, diphtheria, anaphylaxis, and the use of insulin in diabetes. The illustrations are for the most part good, but the coloured plates of the commoner skin diseases and the neutro exanthemata are of little value.

The author of *Elementary Hygiene for Nurses*<sup>8</sup> states that the book has been written in accordance with the syllabus laid down for the final examination of the Australian Trained Nurses' Association. The third edition, which is now before us, is devoted to preventive medicine, and, although entitled "elementary," deals very thoroughly with each subject, and should therefore prove a useful reference book to students and practitioners. English standards have been adopted throughout. The final chapter, on health nursing, is very helpful, as it gives the official requirements a woman must fulfil to qualify as a school nurse, tuberculosis nurse, industrial welfare nurse, child welfare nurse, and health visitor. The appendix is packed with useful information, such as percentage solutions, incubation periods, animal parasites and methods of destroying. An index completes this useful manual.

As might be expected in a book from an American source, Dr. H. C. FALK's *Operating Room Procedure for Nurses and Internes*<sup>9</sup> errs on the side of overloading the curriculum so far as nurses are concerned. With a view to bringing about more efficient co-operation between the surgeon, his staff of assistants and nurses, Dr. Falk has written nearly 400 pages on operation-room procedure alone. In his foreword Dr. EUGENE POOL says that the nurse gathers her knowledge largely from experience and receives too little organized and systematic teaching. With Dr. Falk's book she might almost think herself competent to undertake the operation. Half the book is devoted to detailed descriptions of various operations, with a large number of illustrations of the different stages. The earlier portion deals with the preparation of the theatre, the table, the dressings, the patient, the operating apparel, and the gloves. There is also a chapter on the manual signal system which has been adopted by Dr. E. H. Pool; it indicates when the nurse has to watch for "wiggling" of the surgeon's little finger.

### NOTES ON BOOKS.

PROFESSOR JULIAN HUXLEY has collected into a volume entitled *Essays in Popular Science*<sup>10</sup> some eighteen articles and reviews. Among them is one on "Thomas Henry Huxley and religion," written at the time of the centenary of his grandfather's birth. The essays on heredity, the determination of sex, the dominant sex, the control of the life-cycle, and the meaning of death convey in clear language the teachings of modern biology. In discussing the inheritance of acquired characters the question whether or not hereditary constitution can be permanently changed by environment is considered, and the verdict of non-proven is returned. The author expresses the opinion that the refusal in 1924 of the Ministry of Health to allow the Battersea and Stepney local health authorities to give practical advice about birth control has merely resulted in making it more difficult for the poor, the timid, and the modest to practise it, while the rich and the less squeamish do so readily. Two-thirds of the volume are occupied by an account of the biological aspects of the frog and the tadpole; here we find a critical discussion of the hypothesis that the endocrine make-up of the various races of mankind is responsible for many of their characteristic morphological differences; the author points out its limitations, and thinks it inconceivable that all or a majority of these differences can thus be explained.

We have received two large volumes on medical radiology<sup>11</sup> prepared by four German writers. The book contains a carefully prepared and well illustrated account of recent work in

<sup>4</sup> *Précis de Nursing Médical et Chirurgical*. Par F. A. Rouget, O.B.E., M.D.Édin. Deuxième édition. Port Louis, Mauritius: P. G. Bumstead, 1926. (Fcap. 8s., pp. iv + 396; 13 figures.)

<sup>9</sup> *Operating Room Procedure for Nurses and Internes*. By Henry C. Falk, M.D. New York and Sons. 1925. (Cr. 8vo, pp. xix + 385; 275 figures. 10s. 6d. net.)

<sup>10</sup> *Essays in Popular Science*. By Julian Huxley. London: Chatto and Windus. 1925. (Demy 8vo, pp. xii + 307; 5 plates, 20 figures. 16s. net.)

<sup>11</sup> *Ergebnisse der medizinischen Strahlenforschung*. Band I and Band II. Edited by H. Hölfer and others. Leipzig: G. Thieme. 1925 and 1926. (Sup. roy. 8vo, Bd. I, pp. vi + 749; 451 figures, 3 plates; R.M. 45. Bd. II, pp. 594; 520 figures, 3 plates; R.M. 52.50.)

connexion with the practical use of  $\alpha$  rays, radium, and ultraviolet rays in treatment. The large amount of detail in the text and the great care that has been devoted to the illustrations will render the book valuable for reference.

The second edition of the elementary work on medicine<sup>12</sup> by Dr. A. von DOMARUS, the first edition of which we noticed little more than two years ago (JOURNAL, June 7th, 1924, p. 1009), has been brought up to date, and most of the omissions to which we drew attention have been made good.

The *Army Manual of Sanitation*<sup>13</sup> marks a considerable development in the measures taken for instructing regimental officers and other ranks of the army in the principles and practice of hygiene and sanitation. Instruction of this kind was first introduced in 1907 by the issue of a *Manual of Sanitation in its Application to Military Life*. The little volume now issued contains eight chapters and ten appendices, and is full of useful illustrations and practical information. A short preface by Sir Herbert Creedy indicates the scope of the book as that of an elementary manual suitable for the non-medical reader. We congratulate the compilers on the production of a volume of exceptional merit. Its sphere of usefulness might well extend beyond military circles, and in many respects act as a guide to those interested in the instruction of the civil population as a whole in the principles of hygiene and sanitation.

Dr. ATWOOD THORNE has written a book entitled *Pink Lustre Pottery*,<sup>14</sup> which will be of special interest to collectors of the antique, since very little attention has been previously given to pink lustre in the few publications which deal with English pottery. The author found many good specimens in the museums at Sunderland, Newcastle, and Etruria (Messrs. Wedgwood), and has succeeded in producing a comprehensive account which is concise and easy to read. The book adds considerably to the available knowledge of this subject, and we suggest that in the next edition figures representing the seasons would be appreciated, since they are rarely published nowadays. Mr. MARTIN A. BUCKMASTER contributes a preface, and the book, which is dedicated to the "many delightful dealers" met by the author, will be found a useful handbook for collectors.

In *The President's Hat*<sup>15</sup> Mr. ROBERT HERRING writes a chatty account of a visit to Andorra, the remote republic in the Pyrenees, which has recently acquired some international celebrity. The book describes the adventures encountered on a walking tour through the country and the surrounding neighbourhood, and conveys a clear and pleasant impression of the customs of the inhabitants. The scenery is illustrated by drawings by Mr. Hubert Williams which add considerably to the value of the book.

<sup>12</sup> *Grundriss der inneren Medizin*. Von Dr. A. von Domarus. Zweite verbesserte Auflage. Berlin: Julius Springer. 1926. (Med. 8vo, pp. xv + 650; 68 figures.)

<sup>13</sup> *Army Manual of Sanitation, 1926*. London: H.M. Stationery Office. 1926. (Cr. 8vo, pp. 134; 66 figures. 6d. net.)

<sup>14</sup> *Pink Lustre Pottery*. By Atwood Thorne, M.B.Lond. With a preface by Martin A. Buckmaster. London: B. T. Batsford, Ltd. 1926. (Cr. 4to, pp. xv + 38; 21 plates. 10s. 6d. net.)

<sup>15</sup> *The President's Hat*. By Robert Herring. London: Longmans, Green and Co., Ltd. 1926. (5½ x 8½, pp. 218; illustrated. 10s. 6d. net.)

## PREPARATIONS AND APPLIANCES.

### *Perincorrhaphy Combined Scissors Needle Holder.*

Mr. W. McK. H. McCULLAGH (London) writes: Attached is the drawing of an instrument most useful in the repair of perineums. The swabbing of the wound, the retraction of the cut edges of

the vagina, the insertion, tying, and cutting of the numerous sutures, requires many hands. I find the equivalent of one is saved by this instrument. The idea was suggested by seeing Mr. Gillies use his scissors needle holder. The assistant swabs and retracts by holding the short end of the last suture. The operator,

by means of the instrument, inserts his suture, ties the suture with the instrument still in his hand, and then cuts the last short end and the long end of his present suture with the scissors in the needle holder. The instrument has been made by Messrs. Allen and Hanburys Ltd., of Wigmore Street, W.1.

## Nova et Vetera.

### DIRECT ADVERTISING IN 1815.

Dr. JOHN F. WALKER of Southend sends us two samples of bygone medical advertising which suggest that the baser sort of practitioners had considerable latitude in making themselves known to the public 111 years ago. Both extracts are from the advertisement columns of the *Times* of August 23rd, 1815, and the phraseology of each is very like that used by the quacks of modern times who exploit sufferers from venereal disease or frighten masturbators into their clutches. The first runs:

**DEBILITY, etc.**—Messrs. GOSS and Co., Members of the Royal College of Surgeons in London, continue to direct their attention to those diseases by which the power of the constitution becomes enfeebled; and their experience in such cases, during a long and successful practice, enables them to offer to persons so afflicted, a safe and speedy restoration to sound and vigorous health. A certain disorder frequently contracted in a moment of intoxication, as also its concomitants, are by their plan of treatment (without restraint in diet or exercise) speedily and effectually cured; and where an early application is made, on discovery of the infection, the complaint is frequently removed in two days. By professing exclusively the cure of such complaints, and in order that they may not be marked by a mistaken few with the obloquy so justly attached to the ignorant empiric, Messrs. Goss and Co. think it but justice to themselves to state, that they have been regularly educated in every branch of the profession (certificates of which, from different hospitals, and testimonials from the most eminent physicians, they have to convince any enquiry) that the success resulting from their endeavours first induced them to quit the practice of the general practitioner; and they presume that their pretensions constitute a fair ground for the unprecedented confidence with which they have, by the public, been so liberally honoured. To be consulted at their house daily, by either sex, personally or by letter, with secrecy, delicacy, and attention. Letters for advice and medicine to contain a bank note.—Goss and Co., surgeons, 13, Bouverie Street, Fleet Street.

The second advertisement, though its authors are less explicit about the possession of a surgical diploma, is equally florid in style.

**RENOVATED HEALTH.**—It has been too frequently the subject of just and general reprobation, that men destitute of the elements of the medical art, have offered themselves as candidates for public patronage in the profession of physic. For the purpose of doing justice to the result of our studies, and experience, and to prevent us from being classed among those empirics whose impudent pretensions have unfortunately for society, been too favourably received we beg leave to submit, to the liberal and enlightened, a faithful statement of our pursuits and acquirement. After having received a regular medical education, as the pupils of Messrs. Grindell and Blizard, whose lectures and practice we carefully attended, as professors and surgeons of the London Hospital, we entered ourselves as students in that justly celebrated school for medical acquirements, the Royal College of

...ruated in the different branches of  
ory and practice of Physic, Chemistry,  
those eminent professors, Drs. Munro,  
Duncan, and Rutherford. We trust  
we shall not be deemed presumptuous in saying that our proficiency and acquirements are not inconsiderable. Having for a long series of years made certain complaints, and the various diseases of debility, the particular object of our studies and practice, it will, we hope, be allowed that we have acquired superior knowledge of their treatment and cure. In slight and recent cases of infection, a perfect re-establishment is completed in the short period of two days, and in those of the utmost inveteracy, where other practitioners have failed of success, a proper perseverance in our plan of treatment insures to the patient a safe and radical cure. Amidst the melancholy variety of disorders which are the effects of a habit long and most unhappily pursued by the youth of both sexes, there are none more alarming or distressing than those debilities which frequently embitter life. To such persons it must be a consoling reflection to know that that they may now, by a new and infallible mode of treatment, be restored to the greatest of all blessings—a strong, manly, and vigorous constitution. In all cases of debility, from whatever cause arising, as well as in every species of certain infection, we may be consulted by patients of either sex, with the greatest secrecy and honour. Hours of consultation at home, from 10 to 3, and from 6 in the evening, till 10 at night. Patients in the country are requested to state the particulars of their case, age, and general habit of living, etc., inclosing a remittance for advice and medicine, when the same will be given or sent to any part of the kingdom. To insure that secrecy so essential to an undertaking, the postage of letters may be added to the account for medicines.—CURRIE and Co., Surgeons, 107, Hatton Garden.

## British Medical Journal.

SATURDAY, DECEMBER 25TH, 1926.

### CORONERS' LAW AND THE REGISTRATION OF BIRTHS AND DEATHS.

It is now twenty-one years since the British Medical Association first drafted a Coroners Bill, and sixteen years since a departmental committee, before which the Association had given evidence, reported in favour of many of the reforms which had been advocated and attempted. Except for certain temporary war legislation, however, no substantial modification of the law had been accomplished when, last year, the Association reviewed the whole subject of the reform of the coroner's court and of the registration of births and deaths. As a result of this review a slightly modified policy was adopted by the Representative Body at Bath, and pressure was once more brought to bear on Government departments with a view to legislation. This preparation and pressure has now borne fruit more speedily than might have been expected from the previous history of the matter. A Coroners (Amendment) Act, 1926, and a Births and Deaths Registration Act, 1926, now stand upon the statute book, both having received the Royal Assent last week. The former comes into operation on May 1st and the latter on July 1st next.

Neither of these Acts is perfect, nor fully in conformity with the policy of the Association. The Coroners (Amendment) Act was a Government measure, and accomplishes so much in the way of reform, and is, on the whole, accepted as so satisfactory, that it is very unlikely that any further alterations will be made in coroners' law for a considerable time to come. The full effect of the Act will, however, not be evident until certain further action has been taken by the Lord Chancellor and the Home Secretary, for the Act follows the not very laudable practice of modern legislation in relation to the powers of Government departments, and gives to them authority to "make rules for regulating the practice and procedure at or in connexion with inquests and *post-mortem* examinations." It is to be hoped that when such rules are issued the present arbitrary powers of the coroner, which have sometimes been gravely abused, will be found to have been wisely regulated. The Births and Deaths Registration Act, on the other hand, was a private member's bill, and, though benevolently regarded by the Government, is of very restricted scope, this being severely limited by the rule that no such bill may contain any provision which imposes a charge on public funds, whether taxes or rates. Nevertheless, something useful has been accomplished by it. Dr. F. E. Fremantle, one of its chief sponsors, was modest enough to claim only that its great merit is to improve the procedure in connexion with stillbirths; but it remains true, as Sir Richard Luce pointed out during the second reading debate, that the inadequacy of the law with regard to death certification and registration is by no means removed by it, and that further legislation is still urgently needed to carry out the policy of the British Medical Association in this regard, both for the safety of the public and to secure justice for the medical profession.

The provisions of these two measures, as they then stood, were set out with some fullness in our leading articles on December 12th, 1925 (p. 1134), and on March 27th last (p. 582). Their progress has been carefully watched since the latter date, and action has been taken from time to time to bring to the notice of Government departments concerned, or to make clear to Parliament, the importance of those points of the Association's policy which seemed to be inadequately dealt with. Some very important changes were in consequence effected in the Coroners (Amendment) Bill during its last stages in the House of Commons. The proceedings were reported at some length in last week's issue of the JOURNAL (at page 1200). These will repay careful perusal. It is now provided (1) that if a coroner is of opinion that a *post-mortem* examination may prove an inquest to be unnecessary, he may arrange for this to be made, and for the medical practitioner making it to report the result in writing; (2) that the fee for such examination and report shall be two guineas; (3) that for attending to give evidence at any inquest, without having to make a *post-mortem* examination, the fee shall be one and a half guineas for each day; (4) that for making a *post-mortem* examination and for attending to give evidence at the inquest the fee shall be three guineas for the first day and one and a half guineas for each subsequent day; and (5) that where there is any charge of improper or negligent treatment of the deceased person by a medical practitioner or other person, such medical practitioner or other person shall have the right to be represented at the *post-mortem* examination. Though the fee for performing a *post-mortem* examination still remains quite inadequate, these provisions are a great improvement on those previously contained in the bill, and thanks are due to the medical members of the Standing Committee, and to Captain Hacking and others, for the amendments effected. It may be noted that Mr. Rhys Davies, both in Committee and subsequently in the House on the Report stage, asked the Labour members to support amendments denying even these small measures of justice to the medical profession. Two other important points emerged from this discussion. On the question of making travelling allowances to medical men performing necropsies or attending inquests, the Under Secretary for Home Affairs stated that the legality of paying such allowances had never been challenged; and on the question of a coroner having power to call for, and pay for, a report from a duly qualified medical practitioner recently in attendance on the deceased if (even without a necropsy) such report might render an inquest unnecessary, it was stated on the same authority that it was open at present for a local council to undertake any reasonable expenditure in obtaining such a report, that fees of half a guinea had been paid, and that, instead of asking for legislation to impose this, the proper course was to get local authorities to exercise their existing powers to provide in schedules for such a fee. "Later," it was added, "backward authorities could be brought into line by the Home Secretary."

It is obvious that, although there is still need for careful attention to the whole field partially covered by these two Acts of Parliament, they do at any rate go some considerable way towards meeting the suggestions of the medical profession that further precautions should be taken with regard to stillbirths, and that the status and position of coroners, and of medical practitioners in relation to the work of coroners, should be more satisfactorily defined and regulated, in their own and the public interest.

THYROIDINE.

[25] 25 1926

THYROIDINE.

LAST week the Chemical Society resolved to award the Edward Frank Harrison Prize for 1926 to Dr. C. R. Harington of University College Hospital. The achievement which has earned this tribute from the colleagues of Dr. Harington has been the synthesis in the laboratory of the active principle of the thyroid gland—the substance thyroxine.

It was only in June of the present year that those who follow the literature of chemistry learnt of the progress of his labours, and discovered Dr. Harington on the very threshold of a complete success. Two papers under his name appeared at that time in the *Biochemical Journal*.<sup>1</sup> The first described a greatly improved method for the separation from thyroid tissue of the hormone in a chemically pure state—a method, moreover, which was not found wanting when pursued in an industrial laboratory. The second paper proceeded to the chemical analysis of the pure substance, and here the classical methods of degradation and synthesis joined in the demonstration that thyroxine was to be represented by the chemical structure:

In one particular only was this formula uncertain. The position of the four iodine atoms could not be definitely affirmed. It had been possible to remove these from the molecule of the natural product. It had been possible by two independent methods to synthesize in the laboratory the iodine-free substance by a series of reactions accurately defining its structure. It had not then been found possible to introduce into the synthetic substance those four atoms of iodine which, in their proper orientation, would create the molecule which is thyroxine. The story as it could be related in our issue of June 26th (p. 1092) was almost, but not quite, complete. It seemed that one more step only was necessary; but it now appears that the key to the problem lay far back in the chain of synthesis, and that ultimate success was to be achieved by introducing part of the iodine into the raw materials of the synthesis.

In a joint communication by Dr. Harington and Professor G. Barger to the December meeting of the Biochemical Society,<sup>2</sup> the final solution of the problem was unfolded. Commencing with hydroquinone and tri-iodo-nitro-benzene—materials which inspired a press report to describe, a little optimistically, the synthesis of thyroxine from "coal tar products and iodine"—a series of classical organic reactions were adapted with masterly tidiness to the issue of a product of the above chemical structure. The substance was chemically indistinguishable from that isolated from thyroid glands. The chemical chapter is complete, the biological story opens. Use was made of the now well established quantitative effect of the hormone on the basal metabolic rate. Two myxoedematous patients were chosen. Their basal rates were respectively 32 and 45 per cent. below normal. Intravenous injection of the synthetic substance was spread over six days to a total dose of 14 mg., and the basal metabolic rates rose, in the first case to 6 per cent. short of normal, and in the second to 3 per cent. above normal. There occurred a coincident fall in body weight and increase in the pulse rate. Such activity was quantitatively as great as

that given by natural thyroxine. Physiologically the two substances were indistinguishable. The structure of thyroxine requires the existence of two stereoisomeric forms, and we may suspect that the thyroid gland, by virtue of that elusive asymmetry of vital activities, synthesizes and employs but one of these isomers. That the substance obtained from the gland is the racemic mixture is due to the inevitable racemization which accompanies the process of separation, and it is not improbable that a resolution of thyroxine into its active forms will show that physiological activity is restricted to one only of these. This form should then be twice as active as the materials yet tested. The methods of physiology must now take the field. With thyroxine to hand there is available a means for the quantitative study of the role of the hormone and the function of the gland. Moreover, a study of the comparative effects of thyroxine and of its iodine-free derivative should provide an interesting exercise in the relation of chemical constitution to physiological activity, and, at the same time, offer some explanation for the association, which has yet to be explained, of iodine with the thyroid. The clinician waits upon and will supplement these avenues of investigation. He will be on his guard against the effects of overdosage, and will watch for the reaction of different abnormalities of thyroid function to administration of thyroxine. He will ask also the comparative cost of the synthetic and of the natural product. He will soon be answered. The series of synthetic reactions is complex, but the favourable conditions are defined and the yields are not meagre. The method is essentially practical, and may well prove economic. As with adrenalin, synthetic thyroxine will probably replace the natural product and those crude gland preparations of so uncertain potency.

The committee which resolved to award the Harrison Prize to Dr. Harington comprised the Presidents of the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry, and the Pharmaceutical Society. Thus have the theoretical and applied interests of a science united to acknowledge the common benefit in a great academic adventure.

HEALTH ADMINISTRATION IN AUSTRALIA.

THE report of the Royal Commission on the health of Australia, referred to in the *JOURNAL* of August 7th last (p. 268), has been under consideration by a conference of Ministers of Health of the Commonwealth and constituent States. The conference, which took place at Melbourne, agreed that the Commonwealth should summon a meeting of professional heads of health departments, with Commonwealth and State statisticians and hospital superintendents, with a view to improving the existing system of collecting mortality and morbidity statistics. With regard to the shortage in Australia generally of highly trained experts in public health, the conference recommended that the Commonwealth should consult the various universities and medical schools, with a view to the establishment of a school of preventive medicine and tropical hygiene for experts and the better teaching of preventive medicine to medical students. The conference agreed with the recommendation of the Royal Commission that there should be a Federal State Council, acting in an advisory capacity, for the purpose of securing closer co-operation between Commonwealth and State health authorities. The general scheme of health administration, recommended by the Commission and intended to be carried out by the Federal Health Council, which is in agreement with suggestions originally put forward by the Federal Com-

<sup>1</sup> *Biochem. Journ.*, 1926, 20, 293, and 300.

<sup>2</sup> *Chemistry and Industry*, December 10th, 1926.

mittee of the British Medical Association in Australia, was approved by the conference. The conference also concurred in general with the recommendations of the Commission on venereal disease, maternity hygiene, child welfare, industrial hygiene, and other matters, and referred certain subjects to the Federal Health Council for consideration in detail. The recommendations of the Commission with respect to the encouragement and development of research were unanimously adopted. The conference endorsed the view of the Commission that co-operation between general practitioners and public health authorities was an essential feature in a health policy. The conference adopted the recommendations of the Commission with regard to health publicity, and accepted a reference, not moved as a definite resolution, by Mr. J. Stopford, Home Secretary and Minister of Health of Queensland, to the effect that the Commonwealth should undertake special investigations and campaigns, as in relation to hookworm, compilation of statistics, and publicity, the States to co-operate and extend to Commonwealth officers the powers and authorities of the State laws. It will be recalled that the Royal Commission was concerned with Commonwealth questions only, as affecting either the Commonwealth itself or the Commonwealth in its relation to States, since inter-State legislation and administration were not included in its reference. There is probably no other single question more important to the health of Australia at the present time than the establishment of effective co-ordination to protect the continent as a whole from invasion by disease from without, and to secure united action between the States and the Commonwealth for the general benefit of all. In the issue of the JOURNAL above referred to we expressed the view that the report of the Royal Commission was worthy to receive the attentive consideration of those in whose hands any legislative or other action might lie. It is matter for satisfaction that procedure has been initiated to make its valuable recommendations operative.

#### THE ORIGIN OF SYPHILIS: NEW WORLD OR OLD?

THE problem of the first appearance of syphilis in Europe has been debated from the time of Christopher Columbus to the present day. From that date onwards there has been a widespread opinion that the disease was brought from America by the sailors of Columbus on the return voyage in 1493. There is, however, no direct evidence of this; that is to say, there is no proof of a sailor having contracted syphilis from an American woman, and contrary opinions have been held on the subject from the first. In a learned work on the origin of syphilis<sup>1</sup> Dr. Gaston Vorberg has collected together what appears to be the entire body of available evidence on the question, and has placed the points at issue in a clear light. The supporters of the American theory, of whom Bloch is the most important among modern writers and Oviedo among the contemporaries of Columbus, rest their case upon the following alleged facts: That a pre-Columbian syphilitic bone has never been discovered in the Old World; that an epidemic outbreak of syphilis occurred at the close of the fifteenth century; that the outbreak synchronized with the return of Columbus from America; and that the spread of the disease followed in the footsteps of Columbus's sailors. It should be premised with regard to the older writers that they were somewhat addicted to the *post hoc ergo propter hoc* type of reasoning, and were apt to see a causal connexion between concurrent events without very close examination. For instance, the fact that syphilis and its remedy, guaiacum, occurred in the same locality was sufficient proof for them that syphilis originated in that locality, since where a disease started there the Almighty would provide

a remedy. With regard to pre-Columbian syphilitic bones, it is a remarkable fact that they are practically unknown; but it has been shown by Hrdlička that the same is true of America. That observer examined thousands of skeletons from all parts of America, and failed to find an undoubtedly pre-Columbian syphilitic bone. Dr. Vorberg, however, gives descriptions, illustrated with good figures, of what he holds to be two syphilitic bones—a humerus and an ulna—which were excavated in 1872 by do Bayo from a burial cave in the Petit Morin valley, and are estimated to date from the latter part of the Neolithic period. Judging from the photographs, few pathologists would hesitate to pronounce them to be syphilitic had they been from a present-day patient. On the other hand, no wary pathologist would care to commit himself to the assertion that there was no other disease resembling syphilis in Neolithic times. Taken by themselves it would be unwise to attach great importance to them, although it is possible that the result of further excavations may enhance their value. With regard to the "epidemics" of syphilis referred to above, they were connected with Charles VIII's disastrous invasion of Italy, in which his armies were decimated by disease. It can readily be believed that, if syphilis existed at the time, it would undergo a rapid increase as the result of that invasion; but Dr. Vorberg gives good reasons for thinking that the epidemics were of dysentery and typhoid fever rather than of syphilis, and he also adduces a considerable amount of evidence to show that the occurrence of syphilis in the trail of Columbus's sailors is mythical. The case for the American theory thus appears to be weak, and for a satisfactory alternative it would seem necessary to await the results of more extensive excavations. Dr. Vorberg has scrutinized the terra-cottas, sculptures, and literature of ancient times for evidence of the Old World origin of syphilis, and has summoned two distinguished historical personages as witnesses—namely, Caesar Augustus and Socrates. Although it cannot be said that the venerated histories of famous men form an attractive subject of study, there is some satisfaction in learning that the alleged syphilitic taint in Caesar Augustus is not borne out by an exhaustive scrutiny of his numerous personal blemishes. Unfortunately, the same cannot be said of Socrates. The author has given admirable photogravures of six different busts of Socrates, and the profile view of that in the Louvre, more particularly as regards the nose, almost compels the conviction that a true bill must be returned in this case. Socrates himself was aware of the defect, for it formed the central point of the discussion between him and Kritobulos on the subject of beauty. "Now take noses," said Kritobulos, descending to personalities somewhat; "would you consider yours or mine the finer nose?" "Well," replied Socrates, "if the God of Noses made noses to smell with, there can, I think, be little doubt that mine is the superior of the two. Your nostrils are directed downwards, whereas my nose is tilted up, so that it can receive smells coming from all quarters." "But surely it is a mark of distinction to have a good bridge? Your nose is flat!" "Yes, but with a nose like mine," said Socrates, "one is able to command a much larger segment of the horizon with each eye." In such fashion was the genial sage wont to inculcate philosophic wisdom.

#### GASPARO ASELLI.

THE series of portraits of Italian doctors and naturalists from the fifteenth to the eighteenth century published by the Italian Historical Institute of the Healing Art contains a woodcut of the celebrated anatomist Gasparo Aselli; with an account of his life and work by Professor Pietro Capparone, the eminent medical historian of Rome. Gasparo Aselli was born at Cremona in 1581, and at an early age became a surgeon in the Italian army, and

<sup>1</sup> *Über den Ursprung der Syphilis*. Von Dr. Gaston Vorberg. Stuttgart: J. F. Neumann; London: Peter Davies, Ltd. (Med. 4to, pp. 111; illustrated. 2s. net.)

acquired considerable skill as an operator. He stayed for a long time at Milan, where he developed a large practice and was created an honorary citizen by the Senate. He subsequently became professor of anatomy and surgery at the University of Pavia. At this period the enthusiasm for dissection of the human body which had prevailed among the earlier sixteenth century anatomists was somewhat on the wane, and was being replaced by a study of comparative anatomy and the experiments on animals which led to important physiological discoveries. The existence of lacteals, which had been described by Herophilus and Erasistratus but subsequently denied, was again demonstrated by Aselli on July 23rd, 1622, at Milan in a dissection of a dog which had been killed during digestion. After verifying this discovery in many other animals he published his observations in a work entitled *De lactibus sive de lacteis venis*. He did not complete his discovery, inasmuch as he traced the lacteals of the mesentery to the liver, where he believed they emptied themselves. It was not until 1651, as we pointed out some time ago (1925, vol. i, p. 711), that Jean Pecquet in his *Experimenta Nova Anatomica*, gave the first description of the receptaculum chyli and the passage of the chyle through the thorax into the innominate vein. The error of the Galenic doctrine that the chyle was conveyed by the mesenteric veins to the liver was thus demonstrated. Aselli died in April, 1626, at the age of 45, and his book was published in the following year. His published work was entirely anatomical. His writings on toxicology and surgical cases have been lost, but the manuscript of his *Observationes Medicæ* is preserved in the Trivulzian Library at Milan.

#### DISABILITY IN READING.

THE first series of the Harvard Monographs in Education are dealing with educational psychology and educational measurement; the subject of special disabilities in learning to read and write has already been dealt with, and Miss Elizabeth M. Hincks has followed this up by an investigation of *Disability in Reading and its Relation to Personality*.<sup>1</sup> Fifteen children, chosen only because of their difficulty in learning to read, and all but one of average general ability, were the subject of investigation, and eleven of them were studied intensively. Psychologically the Stanford revision of the Binet test was employed, and the tests of the mental processes concerned in reading were arranged in visual, auditory, and motor categories. Many non-readers are left-handed—a third of the fifteen children investigated were, thus contrasting with the normal 4 per cent.—and many who are not actually left-handed present traits which might be called "left-minded"; they begin to read a word from the right instead of from the left, "was" and "saw" being often bugbears for all non-readers. Miss Hincks is inclined to support the suggestion that some early transfer of handedness may have caused a disturbance similar to that of stammering, but resulting in difficulty in reading. There is much evidence of the influence of heredity, both from the literature and because in nine out of the eleven children tested there was a family history of difficulty in reading or spelling; either in the children or their families there was evidence of nervous traits, such as nightmares, hesitant speech, wilfulness, rudeness to elders, and emotional outbursts of crying. The eye movements, illustrated in a plate, of the children were irregular and uncertain, but improved, as did their behaviour, when, as the result of teaching, their power of reading got better. All the children showed very poor perceptions and memory for words as wholes, many lacked interest to the point of positive aversion for reading, and

readily became fatigued thereby. Upon intensive psychological study they all, with one possible exception, showed difficulties and irregularities in the mental processes which are generally accepted as of primary importance in reading. The evidence brought forward is in favour of the underlying cause being a neurosis, and against the disability being due to congenital word-blindness, and therefore incurable.

#### MEDICAL EDUCATION IN CHINA.

MEDICINE as taught in Europe and America tends to assume certain national characteristics, and it is possible to recognize distinctive features in the different countries and universities. In China, however, medical education on a scientific basis is primarily cosmopolitan; besides the Chinese medical schools there are institutions founded and controlled by other nations, including Great Britain, the United States, Japan, France, and Germany. An attempt to depict the present state of medical education in China has been made in the August issue of the *China Medical Journal*. The only previous educational number of our contemporary was issued in September, 1909, when the editor, Dr. W. H. Jeffreys, defined the ideal of the time as being the laying of the foundations of a truly scientific practice of medicine in China, and the provision of a scientific medical literature. Of the thirteen medical schools described in that issue seven have disappeared, and there seems to be some diminution in the supply of medical graduates trained on the lines of Western science. Nine medical schools are described in the recent issue of the *China Medical Journal* as having educated 650 students, and it is estimated that, including the output of other schools in China, and also those Chinese who have graduated in Europe, America, and Japan, there are only about 1,500 to 2,000 practitioners of modern scientific medicine for a population of 450,000,000. About 500 medical students are at present receiving instruction in the nine schools, which are situated in Peking, Mukden, Changsha, Shanghai (two), Shantung, Chengtu, Hangchow, and Canton. Including students in other schools of lower grade, or attached to foreign medical schools, the number under instruction amounts to 1,000, of whom fewer than 200 graduate each year. Since there are about 600 mission and Chinese hospitals organized on Western lines the shortage of trained medical practitioners is obvious, and the difficulty can scarcely be dismissed as light-heartedly as by one of the leaders in the recent disturbances, who remarked: "We do not want your hospitals; there are so many people in China that the death of a lot doesn't matter." Some such callousness was manifest in the closing of the Canton Hospital, mentioned in our issue of April 24th (p. 753). We understand that regret for this action has been expressed, but the restoration of the activity of the hospital and its medical school is a far more difficult problem than its short-sighted assailants realized. Other hospitals which have been similarly afflicted include the school at Kung-Yee, which was one of the finest of the Chinese institutions, the Stout Memorial Hospital at Wuchow, and the Kerr Hospital for the insane, one of the only two mental hospitals in China. Dr. E. V. Cowdry, in a critical examination of the past divergence between arts and medicine in China, concludes that, while this has seriously hampered the propagation of knowledge about the laws of health, yet the future is by no means dark, since the Chinese more than any other people have always held learning in high respect. He believes, therefore, that when a strong Government is established there will be a great twentieth century renaissance in China, provided only that the spread of knowledge among the masses does not breed the contempt which springs from familiarity. The present editor of the *China Medical Journal*, Dr. J. L.

<sup>1</sup> Harvard Monographs in Education, Series I, vol. ii, No. 2. Cambridge, Mass.: Harvard University Press; London: Milford, Oxford University Press, 1925. (Sup. roy. 8vo, pp. 92; 1 plate. 6s. net.)

Maxwell, reviews in another article the highly controversial subject of preliminary medical training, and contrasts the British view that the medical authorities need only fix a standard to be reached with the American requirement that the medical authorities must themselves prescribe the quality and duration of this instruction. In China a middle course has been steered hitherto, but the tendency is now towards the adoption of the British custom of allowing such preliminary education to be undertaken outside the medical schools, which only reserve the right of testing the degree of proficiency reached by the students. A pre-medical syllabus was approved by the China Missionary Medical Association in 1920, and covers two years' work in biology, chemistry, and physics. Though this syllabus has not been wholly adopted by any one school, it has proved to be a very valuable standard of reference for the medical schools and for the other institutions which cater for intending medical students.

#### THE MALARIA COMMISSION IN SPAIN.

All measures directed to the repression of malaria in Spain were in 1924 placed under the charge of the Central Malaria Commission, which now forms a section of the Third Division of the General Public Health Department at Madrid. It possesses authority to pronounce districts infected, to form district malaria boards, to set up dispensaries, and to issue quinine. The dispensaries control the local work of the Commission in infected districts. They number about twenty in all at the present time. They provide for clinical and blood examinations, the treatment of the sick, the following up of suspects, the issue of quinine, and the suppression of mosquitos. They were supervised at first by medical officers from the central department; they are now in charge of local medical men who have undergone a special course of training. One of the aims of the Commission was to make a general survey of the prevalence of the disease. Malaria is not compulsorily notifiable, but mortality records for 1924 show 1,195 deaths, equal to a general death rate of 5.5 per 100,000. A local death rate may rise to 20 (as in Huelva) or 60 (as in Caceres) per 100,000. The morbidity figure for the whole country has been computed at 300,000 cases annually. Treatment of the sick to a final cure is another object of the Commission. To it is given the place of honour, and it has played a conspicuous and useful part in the plan of working. The propaganda campaign, on the other hand, has had but limited success. The people in many cases will not set themselves seriously to wage war upon the mosquito, or adopt the use of mosquito netting or wire-gauze proofing for their houses. The opinion is commonly held that malaria is apt to prevail near marshes or in wet country, where mosquitos abound. Spain presents the anomaly of malaria due to water deficiency. Such at least would appear to be the case in its most seriously infected districts. Owing to the dryness, agricultural lands are irrigated by artificial channels containing exposed slow-moving water in which mosquitos can breed. So, too, with water for domestic purposes; the rainfall of the wet seasons is led into artificial ponds or tanks near houses, and stored in the open accessible to mosquitos. So, too, even with natural watercourses; the hill torrents, which run full in winter, dry up in summer to a chain of pools. In all these open pools and channels, whose existence about the haunts of men is due to local shortage of water, anopheline mosquitos develop, and emerge to propagate malaria. The plan of implanting *Chara foetida* and *Chara fragilis* in streams to act as killers of anopheline larvae is not encouraged by the experience of the Commission. Better results have been obtained through the activities of the fish *Gambusia*, introduced as a larvicide from the United States in 1921. It feeds on the larvae

freely, and seems to have become well acclimatized. Rice fields, such as those in Valencia and Tortosa, are not thought to be specially dangerous as centres of infection provided their irrigation systems are carefully attended to. The lower the social and economic condition of the people, the higher is the malaria rate. The better sort are more alive to the need for precautions, and have readier access to medical aid. A good medical service for the treatment of the sick is a powerful factor in the protection of the sound, since a patient from whose blood the plasmodium has disappeared does not infect mosquitos. The seasonal movements of agricultural workers, acquiring infection in one place and carrying it to another, have a notable effect in disseminating the disease through the country districts. The most prevalent form of malaria in Spain is tertian, but the quartan fever is common. The tropical variety is comparatively infrequent. The vector is *Anopheles maculipennis*. The disease in general is not of a severe type, and its incidence has declined in recent years, but it still occasions much sickness. The protean character of the malaria problem, to which we referred in a recent article, is well brought out by the work of the Commission. The local activities have already been productive of benefit, and the plan of campaign, if persevered in and extended, should produce greater benefit still.

#### THE CURE OF ANKYLOSIS OF THE KNEE.

For many years surgeons have been striving to find a means of restoring movement and usefulness to ankylosed knee-joints. Dr. Charles-Henri Chevallier, in an excellent monograph<sup>1</sup> just published, has described their efforts and the steps by which success has been achieved, so that in 1923, after Putti of Bologna had demonstrated his methods and results to the International Congress of Surgery in London in 1923, it could be said that arthroplasty of the knee-joint is no longer a hazardous operation but a well established proceeding, giving far better results than the stiff straight ankylosed knee which used to be aimed at as the best functional result. It is fitting that this plastic operation should have been brought to its present state of technical excellence in the city of Tagliacozzi. After relating the work of Murphy, Hoffa, Payr, Baer, and MacAusland, all of whom obtained good results, Dr. Chevallier describes the modification of Putti's operation which he prefers. The following are the conclusions to which Dr. Chevallier has come; we commend them to our readers. In ununited fractures we find false joints which approach in their anatomy to normal joints, and these are due to the interposition of soft parts between the bone-ends. Experiments on animals support this view. A straight ankylosis of the knee ought no longer to be considered a happy result after injury or disease. In suitable conditions arthroplasty is the operation of choice, but not a routine operation. The best method at the present time is that of Putti, in which, after clearing and shaping the ends of the bones, a free strip of fascia lata is interposed between them. The operation is only the beginning of the treatment. The functional result depends almost entirely on the will-power and perseverance of the patient. Improvement in the new joints thus formed goes on for years; gradually they approach nearer and nearer to the normal, but are fortunately less liable to infections conveyed through the circulation. One of the earliest successes—an officer operated on by Payr—had subsequently a suppurating compound fracture of the lower third of the femur without any effect on his factitious knee-joint. There are recorded more than 440 arthroplastic operations on the knee by various methods. Of the sixty-three cases reported by Putti, more than 83 per cent. were successful.

## England and Wales.

### KING EDWARD'S HOSPITAL FUND.

THE PRINCE OF WALES presided over the distribution meeting of the King Edward's Hospital Fund for London on December 14th, and read a letter from the King expressing his sympathy with the objects and activities of the Fund, and his satisfaction that it had been found possible to distribute the same amount of money as last year.

Lord Revelstoke, honorary treasurer, stated that the income for 1926 was less by about £18,000 than that for 1925, mainly owing to a decrease in the amount of legacies; fluctuation in the money received from this source was a contingency that had always to be remembered, and the prudent action of the council, last year in retaining the sum of £9,000 had enabled the amount available for distribution to be maintained at £245,000, although the income had only been £236,000. The British Charities Association had contributed £15,000, as compared with £20,000 last year; donations, however, had increased from £22,829 in 1925 to £27,300, mainly owing to generous gifts of £10,000 from Mr. Albert Searle and of £7,000 from an anonymous donor, who had previously supported the Fund on more than one occasion. A grant of £39,750 from the Wells legacies increased the sum received so far from this source to £192,240, of which £177,750 had been distributed. Sir William Collins, making the annual statement on behalf of the League of Mercy, said there had been a falling off in some districts, attributed variously to the coal dispute, to the competition of contributory schemes, and to the practice of asking for payment from patients. The British Charities Association had provided £5,000 for distribution to voluntary hospitals in almost every county in England and Northern Ireland. The total contributed to the King's Fund by the League of Mercy now amounted to £398,034.

Sir John Rose Bradford, P.R.C.P., vice-chairman of the Distribution Committee, in his report, said that the amount allocated for recovery and convalescent branches, was £243,000, the same amount as last year; a further sum of £2,000 was available for convalescent homes not attached to particular hospitals. The number of hospitals applying for grants was 136, as compared with 133 in 1925. There had been a further reduction in the hospitals showing deficits for the year, the total of available beds had been increased, and many new extensions had been undertaken. Grants towards extensions and improvements amounted to £35,475, as compared with £28,925 in 1925, while £207,525 was distributed for maintenance, as compared with £214,075 in the previous year. These figures were additional to £39,750 in grants to schemes of capital expenditure out of the Wells legacies; the total distribution for the year was thus £282,750. When all the extension schemes which were now being actively promoted by London hospitals had been completed the number of available beds would be 1,632 more than at the end of 1925. The rule had been not to assist in the establishment of new hospitals, or to entertain applications for grants from hospitals which had not been in existence in a properly constituted form for at least three years; the Distribution Committee now suggested that this rule should not apply to new hospitals required for areas where new populations had grown up since the date of the foundation of the Fund.

Lord Sömerville, honorary secretary, presented a schedule containing a list of awards to hospitals, including recovery and convalescent branches. Among the larger grants were:

London Hospital, £15,625; Guy's Hospital, £11,500; St. Thomas's Hospital, £10,500; Royal Northern Hospital, £8,450; University College Hospital, £8,000; King's College Hospital, £7,500; St. George's Hospital, £7,050; St. Bartholomew's Hospital, £7,000; St. Mary's Hospital, £6,500; West London Hospital, £6,250; Charing Cross Hospital, £6,000; Westminster Hospital, £5,900; Metropolitan Hospital, £5,500; Royal Free Hospital, £5,500; Prince of Wales's General Hospital, £5,350; Royal National Orthopaedic Hospital, £5,000; Queen Mary's Hospital for the East End, £4,650; Miller

General Hospital, £4,575; Queen's Hospital for Children, £4,175; City of London Hospital for Diseases of the Heart and Lungs, £4,100; Hospital for Sick Children, £4,000.

After Sir John Rose Bradford had presented the report of the committee on the distribution to convalescent homes not attached to particular hospitals, and the special distribution to hospitals out of the Wells legacies, the Earl of Donoughmore, chairman of the Management Committee, reported on the scheme of pensions for hospital officers and nurses. Many hospitals had already adopted the scheme; it was felt that the hospitals would be enabled to deal in a businesslike way with the problem of the superannuated hospital officer, and that the removal of uncertainty about the future would attract women into the nursing profession.

The Prince of Wales expressed his satisfaction that the receipts had been well maintained; the settled policy of the Fund was to increase distribution as far as could be done without incurring the risk of subsequent reduction. During 1925 more hospitals had reported a surplus of income over expenditure than in any other year since the war. Voluntary gifts had increased by £98,000; patients' contributions by £74,000; building receipts by £364,000; and the total receipts of all kinds for the year had reached the fine figure of £3,887,000. The hospitals, however, still required as much help from the King's Fund as before, because their work was growing as fast as their income. More beds had been made available, and still more were being provided. It was a mistake to suppose that the voluntary hospital system was incapable of expansion. The Fund was, therefore, asked to assist in maintaining the additional wards that were already open and in building others; more building schemes would be undertaken, and demands on the King's Fund would increase. The Wells legacies had helped to add 1,000 beds to the hospitals of London; to increase substantially the provision for dealing with accidents; and to meet the needs of the newly populated areas in outer London, where in some cases it was necessary to build a hospital, since none had previously existed. The income of the Hospitals Savings Association, which was quite independent of the King's Fund, although the Fund had helped to start it, had already reached £150,000 a year. Another enterprise which the King's Fund had assisted at its origin was the pensions scheme for nurses and hospital officers; this had now been taken over by the hospitals. The revised uniform system of hospital accounts, which had come into force this year, had been generally adopted in London as a condition of grants from the King's Fund, the Sunday Fund, and the Saturday Fund; in the provinces it had the backing of the Voluntary Hospitals Commission and of the Joint Council of the Order of St. John and the British Red Cross Society. The Propaganda Committee was thoroughly established as a valuable auxiliary to the Revenue Committee, and more than 200 applications by exhibitors for the hospitals film had been received. A vote of thanks to the Prince of Wales, moved by Lord Stanmore, was seconded by the Lord Mayor, Sir Rowland Blades, M.P., and carried with acclamation.

### CANCER CAMPAIGN IN YORKSHIRE.

The University of Leeds has adapted and equipped the two houses which, as we mentioned on August 14th (p. 320), have been acquired on a five years' lease for cancer research, pending removal to the new laboratory which is to be built by the University with the £25,000 given by Sir Algernon Firth. The two buildings have been converted into one. The chemical department occupies the ground floor, where there are two laboratories and a balance room for the use of Mr. H. J. Channon, who has previously been associated with Professor Drummond in the work on vitamins. On the first floor is the laboratory for the director, Professor R. D. Passey, and another laboratory for the assistant director, Mr. J. S. Young. The second floor contains a small room for experimental work, and an animal room fitted up for keeping the fowls required. On the same floor there is accommodation for one or two research students. Research work will, it is expected, be commenced in the building on January 1st, 1927.

## ADULTERATION OF FOOD AND DRUGS.

The Ministry of Health publishes as a separate pamphlet the portion of its annual report which deals with its work under the Sale of Food and Drugs Acts. It is interesting to learn of the iniquities to which purveyors of food will descend, oblivious, apparently, of the fact that they must themselves consume food similarly adulterated by members of their class, even if they take care to avoid their own products. From the report for 1925-26 the manufacturer or producer seems to be just as guilty as the vendor. Thus an expensive preparation of cod-liver oil and malt was declared to contain all the virtues of the original preparations without the usual objectionable taste and stickiness. As a matter of fact the oil had been "hardened" and deodorized, so that the preparation was almost entirely devoid of vitamin A. Another manufacturer sold alleged ground almonds which were found to consist of ground apricot kernels. There is no need for surprise, therefore, that a street vendor in Hackney was found selling tea which contained iron filings and pieces of wire and nails. It is conceivable, in fact, that in many cases the vendor has been taken in by the manufacturer; as might have been the case, for instance, with the consignment of 9,000 chocolate Easter eggs, which were condemned as unfit for food because they contained quartz, glass, zinc, copper, and sand! Another ingenious manufacturer was under the impression that he had converted a chemically preserved and flavoured cordial into a "non-alcoholic invalid wine" by introducing a trace of quinine. In many cases it seems as if the manufacturer was experimenting to see how far some comparatively harmless adulterant would be tolerated. Thus in one packet of shredded suet—the form in which suet is now generally sold—one-third of the contents consisted of rice flour; and in a sample of custard powder stated to be made from real eggs the proportion of egg was considerably less than 5 per cent. As usual, cases of adulteration of milk were numerous. Practically one-twelfth of the milk examined was adulterated or below standard. A common defence in milk cases is that the cooling apparatus leaked. Sometimes, it appears, the leak is artificially produced. Six and a half per cent. of the total of all samples of food and drugs were found to be adulterated or not up to standard—a higher percentage than was found in 1923 and 1924.

## MEDITATIONS OF AN M.O.H.

Dr. Cameron Kidd, Medical Officer of Health to the Bromsgrove and North Bromsgrove Urban Districts, does not confine himself in his reports to bald statements about the births, deaths, infectious diseases, and drains of his area. He prefers to regard the annual report as giving him an opportunity of ventilating his criticisms of sundry anachronisms, lay errors, and modern panaceas. Thus of erysipelas he says: "As far as any practical use goes this disease might be omitted from the list of notifiable diseases. . . . The medical attendant can surely be trusted to do what is necessary." He has been struck by the succession of ailments from which children suffer as the result of being sent to school at the age of 4, a tendency which is increased by the fear the mothers feel of the school attendance officer. Dr. Kidd says that his eye has been caught by paragraphs in daily papers proclaiming that "science has made consumption little more harmful than the common cold"; a statement which, he says, at the very least is misleading to the public. He holds strong views on the subject of birth control; he thinks that the really enlightened philosopher would prefer infanticide, for which arguments similar to those heard in the House of Lords debate last April can easily be used. Perhaps Dr. Cameron Kidd's feelings on birth control have been unduly aroused by the receipt of numerous advertisements offering him a commission if he will recommend to his patients various contraptions with euphonious labels. From the rest of the reports it appears that the health of Bromsgrove and North Bromsgrove is very satisfactory, though quite a large proportion of infantile deaths in the former district were due to premature birth and atelectasis. Even here, however, Dr. Cameron Kidd suspects the machinations of birth control.

## Scotland.

## HEREDITY IN MENTAL DEVELOPMENT.

A LECTURE entitled "Hereditry, with special reference to feeble-mindedness," was delivered on December 9th by Dr. F. A. E. Crew, director of the animal research department in the University of Edinburgh, under the auspices of the Edinburgh Women Citizens' Association. Evidence derived from the study of the family histories of the mentally defective strongly suggested, he said, that feeble-mindedness was definitely a hereditary character transmitted from generation to generation in an orderly fashion through some existing mechanism. Objection might be raised to this view, because it seemed to disregard the very powerful influence which environment and training exerted during the development of mental qualities. Feeble-mindedness was an oft-quoted instance of a typical recessive character, but until this condition had been defined exactly, and it had been shown what acquired physical aberrations might lead to its development, it could not be finally accepted that a single factor difference existed between feeble-mindedness and normality. Pedigrees in which an unusual number of individuals of subnormal characters were present undoubtedly gave the impression that something was definitely being inherited. The conclusion was at least justified that to a considerable degree mental attributes, particularly those involving general ability and capacity, were based upon inherited factors. What was inherited, however, was only a capacity or predisposition, and what developed from it was in great measure dependent on environment and training. A person of average mental endowment who had developed himself to the full powers of self-expression was often more valuable than one of greater gifts who through indolence or lack of opportunity had failed to develop them. The latter person might, however, be a more desirable parent from the point of view of the race. Before education could advance humanity far, humanity must be capable of profiting by education. The present social fabric was full of weak patches which, under the present sentimental type of legislation, were protected at the expense of the sound parts. It was only when the general level was raised by sound legislation and higher morality that the teacher could find a good field for his activities.

## DAIRY RESEARCH IN SCOTLAND.

A considerable amount of discussion has arisen in regard to the decision of the Secretary of State for Scotland to place the management of the Dairy Research Institute, for the establishment of which an estate at Auchincruive, Ayr, and funds were recently provided by Mr. John M. Hannah of Girvan, outside the control of the governors of the West of Scotland Agricultural College. At a meeting of the governors of the college, held at Glasgow on December 10th, when Sir David Wilson, Bt., was in the chair, a communication from the Board of Agriculture was read, in which it was explained that the Secretary of State realized the importance of dairy research in Scotland, and suggested that the National Dairy School should be removed from Kilmarnock to Auchincruive, and that its management should be vested in a joint committee representative of the Agricultural College and of the University of Glasgow. The governors of the Glasgow College agreed to accept these recommendations, and to give the desired support to the establishment of the Dairy Research Institute at Auchincruive.

## WELFARE OF CHILDREN.

The special aspect of child welfare consisting in the protection of the child against ill-usage or neglect by parents or other natural guardians was discussed at the annual meeting of the Edinburgh District Branch of the Royal Scottish Society for Prevention of Cruelty to Children, held in the City Chambers, Edinburgh, on December 7th. The report showed that during the past year 7,445 cases, involving 21,807 children, were reported to the society. Of these, 280 were submitted to the Procurator-Fiscal for prosecution, and in only 10 were the

persons charged acquitted. Most of the complaints arose in thickly populated districts, although a few occurred in rural areas. More interest was now being taken by the community in matters affecting child life, and legislation had granted powers to public authorities enabling them to devise schemes for strengthening the physical nature of the child, and even the rights of parents had been declared to be of secondary importance to the welfare of their offspring. There was some fear that the duties imposed on public authorities for improving the surroundings of the child might tend to confirm careless parents in laxness and indifference. The Lord Provost, who was in the chair, said that so long as parents were found who were totally regardless of their obligations to their children the need for this society was obvious. Professor Paterson said that, while many people nowadays were expressing faith in eugenics and the segregation of those unfit for parenthood, he personally had a great deal of faith in Nature, which he regarded as more satisfactory than the selection of suitable parents by a medical board. Nevertheless, it was true that in old days many children died of starvation, and that many at the present time were in circumstances in which they would starve if it were not for the public authorities. He also referred to the millions of money spent on educating children and to the activities of various associations connected with the Church. The chief causes of child neglect were intemperance, immorality, and gambling; it was surprising how prevalent gambling had become.

#### PUBLIC HEALTH IN DUMFRIES.

It has been announced that the appointment of medical officer of health for the Burgh of Dumfries has become vacant, owing to the resignation of Dr. Joseph Hunter, who was a part-time officer. The question of a successor has therefore arisen, and a number of local practitioners have signed a round-robin in the following terms:

We, the undersigned medical practitioners of Dumfries and Maxwelltown, are unanimously of opinion that when the appointment of a medical officer of health comes to be made for the Burgh of Dumfries a whole-time medical officer be appointed, and that a deputation of practitioners would be pleased to meet the Public Health Committee of the town council with a view to discussing the matter.

We welcome this evidence of interest in public health administration on the part of the local profession—an interest which has been such a notable feature of the recent work of the Dumfries and Galloway Division. Though the proposal which has been made to the local authority does not appear to be the decision of the Division, we feel sure that it will receive the careful consideration it deserves.

#### SOCIAL SERVICES IN SCOTLAND.

A meeting of the representatives of Scottish organizations interested in welfare work in Scotland was held in Edinburgh on November 12th for the purpose of forming a Scottish Council of Social Service. Sir John Lorne Macleod, who was in the chair, said that the same problems existed in separate areas, and a meeting ground for exchange of views and ideas had frequently been desired. A National Council of Social Service had been formed some years ago in England and had proved its usefulness and value in many directions. It should be clear that there was no intention of conflict with the existing public services. Voluntary effort had a great tradition of social service, and many social provisions now recognized as services for which the community was responsible had been initiated by voluntary enterprise. The council would be primarily a consultative body and should contain representatives of all branches of social effort. It would be able to frame suggestions for the local organization of voluntary work in relation to the work of local authorities. Captain Ellis, D.S.O., M.C., secretary of the English National Council, explained that this body, after its formation in 1919, had helped in the establishment of local councils, and there was now growing up in England a new movement along the line of co-operative community effort which would have a marked effect as time went on. Colonel J. M. Mitchell, secretary of the Carnegie United Kingdom Trust, said that the trustees were satisfied that the theory of a National Council was right. If, however, the council

hoped to have help from the trustees, this could only be for a limited period. A resolution was unanimously adopted to form a provisional committee to consider the proposal in all its aspects and to report.

#### EDINBURGH SAMARITAN SOCIETY.

The report presented to the forty-eighth annual meeting of the Samaritan Society of the Royal Infirmary at Edinburgh on December 7th showed that during the past year 435 cases had been dealt with and 15,078 visits had been paid by the almoners of the society, who had also paid 606 visits in connexion with the social service scheme of the Royal Infirmary. The number of visits paid by the almoners had been more than during the previous year, and 3,800 garments had been distributed, as compared with 3,000 during the previous year. Cash payments to the amount of £1,825 had been distributed, an excess of £285 over the receipts. Mr. Henry Wade, C.M.G., F.R.C.S., in seconding the resolution, expressed on behalf of his colleagues the opinion that the society was an indispensable and integral part of the work in the hospital.

## Ireland.

#### ULSTER MEDICAL SOCIETY.

CLINICS in Canada and America were visited this autumn by Dr. C. G. Lowry, professor of midwifery, Queen's University, Belfast, and Dr. R. M. Beath, assistant radiologist to the Royal Victoria Hospital, Belfast, and at a meeting of the Ulster Medical Society on December 2nd, with the president, Dr. Nolan of Downpatrick, in the chair, an account of this visit was given. Professor Lowry said that he had visited the obstetrical and gynaecological hospitals at Montreal, Toronto, Chicago, Washington, New York, and Boston. The buildings tended to the "sky-scraper" type, with a free use of electric elevators. Special attention was given to ensuring quiet, and the rubber flooring used wore well, was easily cleaned, and did not stain. In some hospitals an electric bell-push was provided for each bed. In maternity hospitals five delivery rooms were supplied for every 100 beds. Green tiles were being increasingly used in operating theatres, as being less tiring to the eyes. The records kept were elaborate, and a great amount of care was taken to make them as perfect and reliable as possible. Many Canadian nurses were trained in Toronto, and the entrance examination to the nursing school was that for matriculation in the university. Their three years' training included maternity work, and the conditions of training, residence, and food were better than those in Great Britain. Maternity wards were often attached to, or formed part of, general hospitals. Great precautions were taken to protect babies in maternity hospitals from all sources of infection, and variation in temperature of the wards was avoided. The chief anaesthetics used were nitrous oxide, oxygen, and ether, followed by ethylene gas, which eliminated much of the post-anaesthetic vomiting; chloroform was very seldom used. Radium had been found to give excellent results in the treatment of cancer of the cervix. The number of students was strictly limited: McGill University admitted only 100 annually for medicine, and there was a long waiting list. The demand for admission to the Johns Hopkins Hospital was also far in excess of the numbers taken. Special study had been made of the 6,000 students in Toronto, who underwent a full medical examination, 2 per cent. being rejected as unfit, and about 5 to 7 per cent. being shown to have some physical disability. Dr. Beath said that the most outstanding feature he had noticed was the unlimited amount of money spent on the provision of apparatus of the newest type selected after careful discrimination.

The annual dinner of the Medical Society was held on December 9th in the Medical Institute, when the President, Dr. M. J. Nolan, Downpatrick, was in the chair, and about 140 Fellows, members, and guests sat down. His Grace the Duke of Abercorn, Governor of Northern Ireland, honoured the proceedings with his presence. The

following toasts were given: "The King," proposed by the President; "His Grace the Governor and Prosperity to Northern Ireland," proposed by the President, and responded to by his Grace the Governor; "The City of Belfast," proposed by Mr. James A. Craig, and responded to by the Lord Mayor of Belfast; "The Guests," proposed by Dr. R. W. Leslie, and responded to by his Honour the Recorder of Belfast, the Vice-Chancellor of Queen's University, and Viscount Bangor; "The Royal College of Surgeons in Ireland," proposed by Mr. P. T. Crymble, F.R.C.S., and responded to by the President of the College (Professor A. Fullerton, C.B., C.M.G.); and "The President of the Ulster Medical Society," proposed by Professor James A. Lindsay. The evening terminated by the singing of the national anthem. It was one of the largest dinners the society has ever held, and much praise is due to the honorary secretary, Dr. Maitland Beath, for his indefatigable labours to make it a success.

#### BRITISH MEDICAL ASSOCIATION AND THE ROYAL MEDICAL BENEVOLENT FUND SOCIETY OF IRELAND.

It is stated in the report of the Royal Medical Benevolent Fund Society of Ireland for the year 1926 that the society received the "hand-ome amount" of £54 4s. from the British Medical Association. The receipt of this sum by the Irish benevolent society was mainly due to those members who effect their life, motor, and other insurances through the Medical Insurance Agency, British Medical Association House, Tavistock Square, London, W.C.1. At a recent meeting of the Irish Committee of the Association a resolution was passed strongly urging Irish members to effect their different insurances through the Agency, as so doing would mean substantial assistance for the funds of the Royal Medical Benevolent Fund Society of Ireland as well as securing for themselves the best unbiased advice with regard to all insurance matters.

## Correspondence.

### FRACTURE OF THE NECK OF THE THIGH BONE IN ADULTS.

SIR,—The discussion at the Royal Society of Medicine on December 6th, and your remarks in the *JOURNAL* of December 11th (p. 1133), will, I hope, be regarded as the funeral dirge and a well timed obituary notice for a type of teaching and practice which has survived too long.

The successful treatment of fractures of the neck of the femur in old people (your remarks refer for the most part to aged subjects) depends upon the proper reduction of the fragments and immobilization for a sufficient length of time. Accurate reduction in the case of a fractured neck is usually less difficult than accurate reduction in the case of a fractured shaft. Secondary displacements during treatment are not so common. Bony union is the rule, and not the exception, and the serious complications which are to be feared after all gross injuries to old people need no special mention in cases of fracture of the femoral neck.

I venture to think that Whitman, who was a pioneer, and those eminent authorities who took part in the discussion at the Royal Society of Medicine, do not realize how widespread is the same weary teaching and the same dreary pessimism which had their origin in the days of Sir Astley Cooper. We still hear of the danger of hypostatic pneumonia, the difficulty of obtaining union between fragments bathed in synovial fluid, the absence of periosteum from the neck of the femur, and so forth. The want of sufficient blood supply to the proximal fragment is an old and worn-out crutch used to support the results of inefficient treatment.

"Such dupes are men to custom, and so prone  
To reverence what is ancient, and can plead  
A course of long observance for its use."

Astley-Cooper's investigations were so imposing in the history of the surgery of bones that to this day posterity can scarcely be persuaded to believe what radiography reveals to its eyes. "The dissections which I have made," says Sir Astley Cooper, "have convinced me that fracture

of the neck of the femur, when it is situated within the capsule, is never united by bone." The writings of Sir Astley Cooper are well worthy of study, but in our literary excavations we must carefully distinguish between the useless debris and the nuggets of pure gold. Dupuytren, on the other hand, pointed to many specimens in the Paris museums of intracapsular fractures united by bone. His methods of treatment were not far removed from the methods recommended by Whitman.

The Royal Society of Medicine discussed in the first place the best routine treatment for practitioners to follow, and afterwards the best course to pursue in hospitals equipped with the necessary skilled staff and appliances. The first is all-important in order "not to embitter the evening of life and compel an otherwise sound person to become an invalid."

To those who have not a skilled staff of assistants and appliances and who have wide responsibilities outside the realm of surgery I think the following hints might be acceptable:

1. The reduction of this fracture is of paramount importance, and is not difficult.
2. Anaesthesia is usually necessary, but need not be prolonged.
3. The limb should be fixed in the abducted position for about three months, and little or no weight-bearing allowed until six months have elapsed. (As in the case of other fractures, the time factor is variable.)
4. Whitman's plaster, Jones's frame, Thomas's splint slung over the side of the bed (the sound limb also in abduction), are effectual for maintaining reduction.
5. Weight and pulley extension without reduction is useless.—I am, etc.,

Dublin, Dec. 12th.

W. I. DE C. WHEELER.

### THE DEVELOPMENT OF VAGINAL OPERATIONS FOR GENITAL PROLAPSE.

SIR,—All who believe that the uterus is maintained within the pelvis by its connective tissue or other attachments seem to omit from consideration the forces at play within the abdomen, especially those occurring during general activity which constantly are tending to produce extrusion. Thus Professor Chipman, at the Congress of Obstetricians and Gynaecologists held in London in 1925, likened the uterus and its supports to a child seated in a swing suspended by ropes. To convert this into a truer analogy, the child and the swing and the ropes would have to be immersed in a medium of much the same specific gravity—for example, water. Suspended in air, the tension of the ropes must be considerable; suspended in water, the tension of the ropes is much less, or even disappears, for the pressure of the water tends to buoy up the swing laden as it is. In the first case, the tension of the ropes is considerable because "gravity" attracts the swing and its contents downwards with much greater force than it attracts the "medium" (that is, the air) in which the swing is "suspended"; in the other case, gravity attracts the water downwards with a force almost as great or as great as it attracts downwards the swing.

I have insisted for many years that the pressure in the abdomen and pelvis, which form a container for the viscera, is not due simply to the effect of gravity; but that in virtue of the musculatures forming the walls, the viscera are continuously compressed, in a degree, however, which varies with the posture and with the state of rest or activity of the individual. And I have shown that this compression of the viscera is related with general metabolism. On the one hand, it is related with the return of blood in the large abdominal veins to the heart (and thus with the aortic blood pressure); on the other, it is related with the flow of blood through the visceral capillaries, and so with the visceral response. Thus the visceral response is greater (within limits) when the average intra-abdominal pressure (the pressure of rest) is greater; and less when the intra-abdominal pressure is below average (as in eutroptosis and neurasthenics). Nor is it difficult to show that the intra-abdominal positive pressure is correlated with the negative intrathoracic pressure—a pressure which

is not simply concerned with the passage of air into and out of the lungs, but especially with the adequate flow of blood through the pulmonary capillaries, which obviously must vary with the needs of the individual.

A study of the levator ani led me to this conception of man. It was seen that the levator ani is not simply the relic of former tail-moving muscles, but that it presents as the most important part of a muscular parietes closing in the pelvic outlet; that in its function it acts as an obturator to the pelvis inferiorly, and not a passive but an active one, to emphasize which I called it the "sphincter of the pelvis." Visceral canals of necessity pass from the pelvis to the exterior; they traverse the pelvic floor, and though they have their own sphincters, when these are lacerated, occlusion of the canals depends on the pelvic floor. But the pelvic floor does not exist simply to prevent the exit of visceral contents: it exists primarily to prevent the exit of pelvic visceral parts.

Unless the viscera in the pelvis can be maintained within the pelvis during times of stress, the pressure within the abdomen, increased during such times, cannot be sustained. Thus the reason of the weakness complained of by many women with genital prolapse is clear. Each time they try to do anything the parts are extruded, or the extrusion is increased; the necessary pressure with the abdomen cannot be maintained. Instead of blood within the large abdominal veins being forced in greater measure to the heart, viscera in the pelvis are forced out of the body to greater extent. Thus the rise of aortic blood pressure, the concomitant of normal activity, cannot occur; all the body parts suffer, the individual feels weak, and in the worst cases is forced to an invalid life.

Although Dr. Nyulasz (November 13th, p. 907) says he has read my books in which this subject is dealt with, he leaves it out of the account when considering the effect of vaginal operations for prolapse. He believes the cardinal ligaments, in virtue of their non-striped muscle content, are the "main supports of the uterus"; and does not accept my statement that they "are not capable of sustaining the pressure which during life is continuously tending to depress the uterus." But if the cardinal ligaments maintain the uterus in the pelvis, how is it that the pressure beneath the uterus, between its cervical part and the pelvic floor—that is, in the ampulla of the rectum—varies with the position of the individual and the activity in play? This is so even when the gut is empty and its walls are opposed to each other, in which case a pressure can hardly be transmitted to it by way of the lumen from higher reaches of the gut. When the patient coughs, up shoots the mercury of the manometer. How could this occur if the cardinal ligaments sustain the uterus in place and prevent its descent or its tendency to descent, which the rise of pressure above, produced by cough, occasions? And each time the patient coughs the pelvic floor musculature can be felt (by palpation) to contract. Why? There must be some reason. If the paracolpos, the parametrium, and the pararectal tissue maintain the bladder, the uterus and the lower rectum in the pelvis, and are adequate to sustain the intra-abdominal pressure in all the phases of life, why when the intra-abdominal pressure is raised is the response of the pelvic floor increased? Why, indeed, should there be a pelvic floor? It is a question that Dr. Nyulasz should answer—and one that Dr. Bride might with advantage consider.—I am, etc.,

Rugby, Nov. 14th.

R. H. PARAMORE, F.R.C.S.Eng.

#### POST-OPERATIVE RADIATION IN CANCER OF THE BREAST.

Sir,—In a discussion following Mr. H. W. Carson's paper on post-operative treatment of cancer of the breast, reported in the *BRITISH MEDICAL JOURNAL* of December 11th (pp. 1095-1097), very diverse views were expressed with regard to the value of x rays as a prophylactic.

To furnish direct proof of the value of prophylactic radiation is almost impossible. Its object is to maintain the *status quo*; and in any case where it is not maintained failure is manifest. On the other hand, where recurrence does not take place there is no certainty that, in an

individual case, the radiation has prevented it. Finally, if recurrences follow quickly it is easy to blame the radiation, forgetting the cases which recur quickly when no x rays have been used. In discussions such as the one above referred to, only rarely does anyone say anything about the technique employed. The idea that all failures and even injuries which result from x rays are quite independent of dosage, frequency, area exposed, and so forth—in a word, that the directing mind does not count—dies hard. Unfortunately, the most diverse technique is employed by radiologists for prophylactic treatment, and in some cases patients are grossly overdosed. This is evident from the statements of some surgeons that their patients feel very ill after a prophylactic course, and ask not to have it repeated. One cannot but sympathize with Mr. Sampson Handley's plaint in a recent discussion at the Royal Society of Medicine that, although he welcomed the assistance of the radiologist, intensive therapy was not quite the sort of help he wanted!

If prophylactic x-ray treatment meant of necessity making a patient feel ill, it could not be justified. The patient may be all right if nothing is done; therefore no risk is permissible. So far, however, from a patient feeling upset after a properly administered course of radiation, she should have gained in strength. It is entirely a matter of the size and spacing of the doses. The dose should be of the order of 1.5 milliamperes, 40 cm. anticathode-skin distance, 3 mm. aluminium filter, 140 to 160 kilovolts; time ten minutes: tube diaphragm widely open. Twelve to eighteen such doses may be given for a course, at first three times a week, and later twice a week. A course of this kind may be commenced, in hospitals, as soon as the patient can be brought to the x-ray department. If there is any raw surface left in the wound, healing will be expedited and the patient's general health rapidly improves. This system is in vogue both at the French Hospital (London) and at the Croydon General Hospital, and is carried out, of course, with the full approval of the surgical staff. Of late we have combined sunlight treatment with the x rays, producing even better results as regards the general health. That the procedure advocated is constitutionally beneficial can be verified by inquiry from the surgical staffs concerned; to prove that it is an efficient prophylactic is another matter. But surgical testimony can be invoked to show that similar treatment is in some instances capable of rendering an inoperable growth operable, or even of causing the disappearance of cancerous nodules. Thus we have at our disposal a line of treatment which is (a) a general tonic, and (b) capable in some cases of bringing about shrinkage of malignant tumours. Not to use it as a prophylactic would be irrational in the case of anyone accepting the above propositions.

Nothing I have written is to be taken as an argument against the use of large x-ray doses in suitable circumstances. Intensive treatment may cause the disappearance of a cancerous tumour where milder measures have failed. But a "negative phase" obtains for a time, during which general body resistance falls; and at this period, should any distant metastases exist, they are apt to spring into activity. Intensive treatment should be looked upon as an alternative to operation in selected cases so far as the primary growth is concerned, and not as an adjunct to surgery. Attempts to use it as a prophylactic in cases which have already suffered from the shock of a major operation have brought discredit upon the method, and have no doubt in some instances tended to favour metastases.—I am, etc.,

London, W.1, Dec. 11th.

F. HERNIMAN-JOHNSON.

#### ANTIGENS FOR THERAPEUTIC IMMUNIZATION.

Sir,—May I supplement the letter you were so kind in publishing in your issue of August 21st (p. 360) in respect of immunogens, as these products have been placed on the market with practically no published clinical evidence, so far as I know of?

Sir Thomas Horder has reported strongly in favour of them, but his paper contains no actual clinical records, and apart from this paper and that by Drs. Ferry and Fisher in the *Journal of Experimental Pathology*, which is concerned only with immunity tests carried out *in vitro*

DEC. 25, 1926]

# CORRESPONDENCE.

THE BRITISH MEDICAL JOURNAL 1243

(personally I do not concede that these have any clinical value, but are merely suggestive), clinical records are as yet unpublished. Doubtless they will be published, but it seems to me that to issue the antigen for sale prior to such publication is scientifically indefensible and wholly wrong in that if, as appears to me from reasons given below, the product is of no value, the only result will be unfairly to discredit vaccine therapy. Here we have a classical example of the evils of commercial exploitation. The anxiety to sell while the going is good can have only one result—namely, that when a really good type of vaccine is evolved it will be received with frigidity by those who have been bitten before.

I have had the opportunity, thanks to the courtesy of Messrs. Parko, Davis and Co., of trying immunogens. Five, far, in fifteen instances, I have been disappointed. Five cases were gonorrhoeal. One was a woman with chronic cystitis and much pus. No amelioration of gonococcus of pus was obtained after several injections of gonococcus immunogen. The infection was a pure one, and the bladder was washed out with weak boric acid and also permanganate. The other four were subacute and chronic cases, having the usual irrigation treatment, massage, sounds, urethroscopy, and so on. My assistant, who sees all the male cases, and myself came to the conclusion that immunogens had no effect for either good or ill on the duration of the complaint.

A case with a renal sinus discharging streptococci and pus was not benefited; a case of staphylococcal skin infection was apparently made worse. Lower dosage with the streptococcus combined immunogen, which contains staphylococcal products as well, was a failure. A patient with profound toxæmia from streptococcal cellulitis seemed to improve at first and then remained stationary until he was put on to antistreptococcal serum (Parko, Davis and Co.), when he began to improve at once, and made a complete recovery. This latter product is in an altogether different class, and is most excellent in its effects. I have used it and watched its use for years, and have a very high opinion of its value.

A case of boils in a mental patient was treated with an auto-immunogen of *Staphylococcus aureus*. At first she did well, and then relapsed completely, and is now on an auto-vaccine.

A case with fulminating streptococcal meningitis was given streptococcal immunogen without effect and died. Likewise a patient with a mixed influenzal and streptococcal pneumonia.

The other four cases were of pneumonia, and appeared to be uninfluenced by pneumococcus immunogen. Three of these were on the original type of immunogen.

Possibly I have been unlucky and others have had better results. If so, their publication is overdue; but, for my part, I still hold that *in vitro* tests are no criterion of what will happen *in vivo*, and that the more mutilated the product the more inert it is, and that the more natural autogenous vaccine is the better agent of immunity.

—I am, etc.,  
GEOFFREY SHERA, M.A., M.D. Cantab.

Eastbourne, Dec. 6th.

## VISUAL STANDARDS FOR MOTOR DRIVERS.

Sir,—The article dealing with visual standards for motor drivers in the JOURNAL of December 18th (p. 1191) draws attention to the American Medical Association's recommendations. These recommendations appear to omit any reference to the field of vision, which is at least as important as the distant vision. My attention was drawn to the necessity for a good field by a case which recently came before me. The patient complained that although he had good sight he had had two minor accidents. In the first, he had collided with a wheelbarrow which had been left at the side of the road, and in the second, in turning a corner, he ran against a standard lamp-post. On examining his eyes I found that he had chronic glaucoma, with which was associated a considerable contraction of the field of vision. The cause of his trouble was obvious—as is the moral.—I am, etc.,

Bath, Dec. 19th.

W. M. BEAUMONT.

TREATMENT OF ACUTE POLIOMYELITIS.  
Sir,—As the unfortunate (or otherwise) medical man connected with Uppingham, may I crave for space for a few less or more disjointed remarks on poliomyelitis and the correspondence therewith.

In the JOURNAL for December 11th three letters appear under the heading "Treatment of acute poliomyelitis." Surely what is meant is "sequelae of," etc. One writer mentions "long view"—a matter of years. The acute stage is a matter of days; it is the paralysis which follows to which the writers evidently refer; and yet when we open a mastoid or drain a chest in empyema we do not talk of the adenoids, measles, scarlet fever, etc., which may have caused the ear trouble, or the pleurisy which was the root cause of the empyema. It is not well to mix up cause and effect. To my mind the treatment of acute poliomyelitis would deal with the invading virus before the cord is attacked. This is what ought to be aimed at, and is within the range of possibility provided an early and correct diagnosis is made. It must be early, for once the virus has settled on any part of the grey matter treatment is useless; we attempt to repair the damage.

In most diseases the reply of the organism to the invader is helpful—not so in poliomyelitis. The increased vascularity adds to the trouble, pressure putting out of action for a time adjoining cells. Further, poliomyelitis is a law unto itself in invasion or spreading. Leicester, with its depressed industrial population—depressed by reason of the coal strike—and without the advantages of Harley Street, suffers on a population basis about one-twentieth of Broadstairs. Evidently the ordinary rules do not apply; then for Heaven's sake why not say so, and try some fresh avenues?

I notice in the leading article in the same issue of the JOURNAL (p. 1129) that the Advisory Committee was called in consultation about a month after the disease appeared at Woolwich, and the date on the Lord Dawson and Dr. Collier Broadstairs circular is October 20th, on which date there were about fifty notified cases in Broadstairs; in both instances the epidemic was well under way. There would in the ordinary course of events be many infected people, with corresponding dangers; it is merely a matter of control versus prevention.

Uppingham dealt with the matter at the very outbreak. Our plans were wellnigh fixed in the event of a second case appearing in the school. Surely modern medicine is essentially intelligent anticipation. Following is no good—get in front and keep there!

During the correspondence on methods many times Pope's couplet comes to mind: "For forms of government let fools contest; what'er is best administer'd is best."—I am, etc.,

Uppingham, Dec. 11th.

P.S.—We had only two cases in Uppingham School and district; this compares well with other centres.—W. D.

WM. DUNN, M.B.

## A MEDICAL ASPECT OF MINERS' SHORTER HOURS.

Sir,—As the son of a miner, I beg to agree with Dr. G. Arbour Stephens's view that the strain of seven hours' work is greater (and worse for the miner) than eight or nine hours' work.

Statistics are wanting, but may I give three examples of long hours, health, and longevity? Mr. Thomas Burt, M.P., the late father of the House of Commons, was healthy in body and mind till over 80 years of age; yet I believe he worked twelve hours a day in the mine. Mr. William Straker, the secretary of the Northumberland miners, is alert in body and mind at 70 years of age; and I believe he also worked twelve hours a day in the mine. My father started work at 8 years of age at 6d. a day in the Weardale lead mines; he worked twelve hours a day, and never saw the sun in winter in his life. He rose through all the grades of mining in lead, coal, and ironstone till he became a leading mining engineer, educating himself after his long hours in the mines; he died at 72 years of age from strain (not work) from running to catch a train with a heavy weight on his back.

These cases appear to support Dr. Stephens's view, whilst I think that Dr. F. G. Bushnell's conclusions that "lower wages and longer hours lower the average physical condition" are open to question, as higher wages and shorter hours may lead to poorer food, pernicious amusements, and drinking habits. As regards the reduction of mining accidents following reduction of working hours in 1919, as compared, say, with those in 1908-12, Dr. Bushnell appears to take no account of the maximum time worked, nor of the greatly improved safety of mining (due to one of the best classes of citizens in the country—namely, the colliery managers). If I ride twelve hours in a motor car I am more likely to have an accident than if I ride only seven hours. And I am more likely to have an accident on a dangerous road than upon a safe one. These points Dr. Bushnell seems to have left out of count. And his opinion to account for the increase in accidents in 1923 and 1924 as due to "a worsening of the miners' wages" (the miners being probably the best paid class of workers in the country) will hardly, I think, bear the weight he places upon it.

In my opinion a healthy man or woman who objects to a life of eight hours' work, eight hours' leisure, and eight hours' sleep can hardly be regarded as an ideal or as an average citizen.—I am, etc.,

Newcastle-on-Tyne, Dec. 12th.

T. M. ALLISON, M.D.

#### THE MEDICAL REGISTER: "UNTRACEABLE" PRACTITIONERS.

SIR,—The letter from "Your Adelaide Correspondent" in your issue of December 18th is likely to give an incorrect impression as to the methods adopted by the Council in regard to the correction of the *Medical Register*.

Once in every five years the *Register* is gone through very carefully indeed with a view to eliminating the names of practitioners who have died, or who have ceased to practise. An inquiry in accordance with the provisions of the Act is issued, and if no answer is received a reminder is sent; in those cases in which no answer can be obtained, or in which the inquiry comes back through the Dead Letter Office, efforts are made to obtain further information.

Section 14 of the Medical Act, 1858, states that it shall be lawful for the Registrar to write a letter to a registered person addressed to him according to his address on the *Register* to inquire whether he has ceased to practise or changed his residence, and if no answer is returned within six months it is lawful to erase the name of such person from the *Register*.

The Council, therefore, is under no obligation to do more than to send an inquiry to the registered address, but, within certain limits, it does what it can to trace practitioners by consulting works of reference, Colonial Registers, the Ministry of Health, and the British Medical Association, and, finally, by publishing a list of names of those in regard to whom no information has been obtained. In view of the fact, however, that there are 50,000 names on the *Register* there must be a limit to the search which can be made.

The officials of the British Medical Association at its headquarters are familiar with what is done, and, I think, would be willing to bear witness to the efforts made to trace practitioners, and to the desire of the Council not to erase names if this can be avoided.

No one who was unfamiliar with the work of this office could realize the great difficulties in getting some practitioners to answer inquiries which are sent to them. Medical men are very much occupied, and often have little time to deal with correspondence which they think is not pressing; but I am glad to say that the consistent efforts of the Council in recent years to impress upon practitioners the importance of keeping this office posted with a safe channel of communication is having its result, and practitioners are realizing far more than they did the importance of themselves notifying changes of address, and of answering inquiries which relate to the *Medical Register*, the only book in which the appearance of their names ensures their legal privileges.—I am, etc.,

NORMAN C. KING,

London, W.1, Dec. 18th.

Registrar, General Medical Council.

#### MOTOR CAR INSURANCE.

SIR,—The Medical Insurance Agency, as a result of two unfortunate experiences which have come to its notice in the last few months, desires to draw the particular attention of medical men to the risks they run inadvertently and the liability which they may incur by taking motor car insurance policies with restrictive clauses.

The two most usual clauses are those by which one named driver only is permitted to drive, and by which the assured bears the first £5 or £10 of any claim. Both these restrictions, although saving some small amount in premium, may easily cause loss—perhaps serious loss—and certainly annoyance in the event of a claim arising.

For instance, if a doctor names himself as the only driver of his car, his car will be uninsured while it is being driven by a mechanic on test after overhaul or being returned to the garage by some other person at the doctor's request.

It is almost certain that there will be disagreement between the doctor and the insurance company or underwriters (where the doctor agrees to bear the first proportion of any claim) in cases where the fault would appear to be entirely with the third party. For instance, if a person be knocked down and killed through his own carelessness, the dependants, especially if there be children, are, as experience has shown, almost certain to be awarded something in the shape of compensation, although the owner of the car has been formally discharged free from all blame at the inquest. Such cases then are nearly always settled out of court, the insurance company and underwriters paying whether they have won or lost, rather than be mulcted in heavy law costs.

Regarding damage done by one car to another, the insurance companies sometimes have an arrangement between themselves whereby each side pays its own accidental damage claims, thus avoiding extensive litigation in assessing the blame. However, it should be borne in mind that such an arrangement between the companies does not prejudice the right of the owners of the vehicles to claim against each other for personal injuries at their own risk.—I am, etc.,

L. FERRIS-SCOTT,

Secretary, Medical Insurance Agency.

B.M.A. House, Tavistock Square, W.C.1,  
Dec. 17th, 1926.

#### Obituary.

DR. LAURA WILLIAMS PUGH, medical officer of the Welsh Board of Health (Ministry of Health), died at her home in Brondre, Machynlleth, North Wales, on December 17th. She was the sister of the late Dr. Robert Pugh, medical superintendent of the Joint Counties Asylum, Talgarth, and received her medical education at Birmingham and Edinburgh, graduating M.B., Ch.B. Edin. in 1908. Later she obtained the D.P.H. of the English Conjoint Board. After serving for some years as assistant medical officer at the West Ham Union Infirmary, Leytonstone, she entered the service of the Monmouthshire County Council in 1914 as assistant school medical officer and medical officer in charge of the maternity and child welfare centres of the county. She was also an approved lecturer under the Central Midwives Board, and in that capacity delivered courses of lectures to midwives at the Tredegar Maternity Home. In 1923 Dr. Pugh was appointed by the Minister of Health to be the woman medical officer of the Welsh Board of Health, her duties including the inspection of maternity and child welfare schemes and maternity hospitals throughout Wales. A colleague writes: Dr. Pugh was a very capable officer, and soon became popular with officials of local authorities with whom she came in contact. She was a woman of strong character, and during her short period of office she succeeded in effecting great improvements in maternity and child welfare work in Wales. In February of this year she entered a nursing home in London to undergo an operation, but unfortunately she was found to be suffering from malignant disease for which no relief could be given. After a short period of rest she returned to her duties with characteristic courage until early in November, when she was compelled to retire. Dr. Pugh was devoted to her

work, and, though she well knew that the end was inevitable and could not be long delayed, she resolutely remained at her post until further work was physically impossible. She never thought of herself, but was always anxious to be of service to others. She was one of the most delightful and loyal of colleagues, and will be greatly missed by those with whom she worked at the Welsh Board of Health and by the medical officials of local authorities in Wales.

Colonel HENRY STOKER died on December 1st at the Royal Military College, Duntroon, Federal Territory, Australia. Dr. Stoker came of a very old professional family of three generations; he was the fourth of seven sons of the late Dr. E. A. Stoker of Dublin, all of whom followed their father's lead, with the exception of one, who selected dentistry. His grandfather (1773 to 1845) and father were leaders of professional thought in their time. Dr. Stoker was educated at Beehive College, Trinity College, and the Royal College of Surgeons (Ireland); he obtained the diplomas of L.R.C.S.I. in 1884, L.R.C.P.I. and L.M. in 1885, and the F.R.C.S.I. and D.P.H. in 1895. He early decided to make his home under the Southern Cross; he was appointed sanitary officer to the Port of Melbourne, and his pioneer work in connexion with fly-borne diseases was valuable. His bent, however, was to surgery, and, settling in Wagga Wagga, he developed a large surgical practice, and became one of the leading operators in New South Wales. On the outbreak of war he joined the Australian Army Medical Corps and saw foreign service; he attained the rank of colonel, and after the cessation of hostilities the Federal Government marked its appreciation of his work by appointing him to the Royal Military College, Duntroon. Interested in all forms of outdoor sports, he will be remembered by contemporaries as a prominent member of the Wanderers Rugby Football Club, playing with his brothers, two of whom reached international standing, while he himself just missed this distinction, being selected for the reserves. Colonel Stoker took an active part in the work of the various medical societies of the Antipodes, and made an excellent president, being materially helped on the social side by his wife (a daughter of the late Mr. James Poe of Kilkenny), who was unhappily killed twelve months ago in a carriage accident, in which he also received injuries. He could not be induced to curtail his activities, but continued his work with a fine courage in pain and sorrow. Colonel Stoker leaves two sons.

Dr. WILLIAM ALEXANDER WADSWORTH, who died on November 21st, was educated at Galway, Belfast, and the Royal College of Surgeons in Ireland. He graduated M.D. R.U.I. in 1884, and obtained the diploma L.M.R.C.P.I. in the same year. Four years later he received the B.Ch. He then commenced private practice in Belfast, and later succeeded his two brothers. He was a magistrate of the city, and was keenly interested in the work of the Carlisle Memorial Methodist Church, of which he was a trustee and a member of the quarterly board for over thirty years. He was a member of the British Medical Association.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

As mentioned last week, Parliament was prorogued on December 15th. The following notes refer to medical matters which arose during the last day. A list of Acts of medical interest which were passed and of bills which for various reasons were abandoned is first given.

### New Acts.

Acts which received the Royal Assent on December 15th and came into force immediately included:

**Housing (Rural Workers) Act**, empowering local authorities to give, with the approval of the Ministry of Health, assistance by grant or loan for reconditioning houses in rural areas provided that for twenty years such houses are occupied by agricultural workers or the like.

**Births and Deaths Registration Act**, requiring stillbirths to be registered; adding safeguards to the law of registration of death and of the disposal of bodies; enabling local authorities to arrange, in certain instances, for the medical inspection of a dead person.

**University of London Act**, setting up a body of commissioners with power to draft certain statutes for the University.

**Wireless Telegraphy (Blind Persons Facilities) Act**.

**Workmen's Compensation (No. 2 Act)**, extending the period during which a review is possible of compensation payments to workers under 21.

**Penal Servitude Act**, increasing the maximum penalties for certain sexual offences.

**Judicial Proceedings (Regulations of Reports) Act**, restricting the reports of divorce proceedings and redefining the law against the publication of indecent details in other cases, including indecent physiological details.

The following statutes, which became Acts on December 15th, come into force later:

**Coroners (Amendment) Act**, regulating the qualifications, appointment and resignation of coroners and deputy coroners, requiring coroners to have either medical or legal qualification, and giving power in certain additional circumstances to hold an inquest without a jury and increasing the fees of medical men for attendance at inquests and *post-mortem* examinations. Comes into force May, 1927, with the exception of Section 4 (abolishing franchise coronerships), which is to be enforced at once.

**Lead Paint (Protection Against Poisoning) Act**, imposing fresh regulations from January 1st on the use of lead paint on internal work, and prohibiting, from November 19th, 1927, with special exceptions, the employment of women and young persons in such work.

**Legitimacy Act**, providing for legitimation by subsequent marriage.

**Public Health (Smoke Abatement) Act**, abolishing the obligation to prove the objectionable smoke is "black," and giving power to take proceedings against the emission of grit, gritty particles, and noxious vapours.

The following Acts of medical importance obtained the Royal Assent earlier in 1926:

**Economy (Miscellaneous Provisions) Act**, reducing by £2,500 annually, from January 1st, the State grant to the Health Insurance Fund, and transferring to the Exchequer a surplus of £1,100,000 from the Navy, Army, and Air Force Insurance Fund.

**Unemployment Insurance Act**, extending the present system of unemployment insurance till December 31st, 1927.

**Boards of Guardians (Default) Act**, authorizing the Ministry of Health to supersede boards of guardians who do not observe the law.

**Adoption of Children Act**, authorizing adoption by sanction of the court.

**Midwives and Maternity Homes Act**, providing for the registration and inspection of maternity homes, amending the Midwives Act, and authorizing a revision of the register of midwives.

**Chartered Associations (Protection of Names and Uniforms) Act**, enabling associations to register uniforms and making the wearing of such uniforms without authority an offence.

Bills abandoned include:

The Factories Bill, Mental Deficiency Bill, Dentists Bill, Offices Regulation Bill, Protection of Animals Bill, Vaccination Bill, and Venereal Disease Act (1917) Amendment Bill. The first was a Government measure.

**Dental Benefit.**—In a reply to Sir Frederick Hall, on December 15th, Sir Kingsley Wood said it was proposed to appoint regional dental officers in connexion with dental benefit treatment as administered by approved societies. Applications for the posts had been invited by advertisements which did not restrict candidature to dentists holding any particular diploma. A Selection Committee had been set up, but appointments had not yet been made.

**Spahlinger Treatment.**—In a reply to Sir Charles Cayzer, on December 15th, Sir Kingsley Wood said local authorities were not encouraged to make use of the Spahlinger treatment for tuberculosis; it was not one of the special benefits to which insurance societies could apply their surplus, and no estimate could be given of the money needed to introduce the system of treatment on an extended scale in this country. The materials for a scientific investigation of the treatment in this country were not forthcoming.

### Notes in Brief.

Out of 11,650,000 persons in Great Britain who are insured against unemployment, 600,000 to 650,000 are estimated to be aged 60 to 69 years.

The use of "brynite" is to be permitted in sausages and sausage meat.

The Home Office will consider whether the Introduction to Criminal Statistics should again give particulars of the apparent causes of murders. This return was discontinued in 1905.

Mr. Amery has stated that in Uganda vaccination was compulsory for all natives over 6 months. Exemption was allowed to persons who previously had small-pox, had been successfully vaccinated within five years, were certified to be unfit for successful vaccination, or were found insusceptible of successful vaccination.

Sir William Bull asked Mr. Chamberlain whether he had been advised on the exact legal position under the Venereal Diseases Act of chemists selling material for prevention together with printed or written directions for its use. Mr. Chamberlain replied, "Yes, Sir."

DEC. 25, 1926

MEDICAL JOURNAL 1247

## MEDICAL NEWS.

### The Services.

The attention of medical officers, R.N., is drawn to Admiralty Fleet Orders 575-23 regarding the institution of the North Persian Memorial Medal. Intending competitors should communicate with the Department of the Medical Director-General before the end of the month.

### DEATHS IN THE SERVICES.

Major Richard James Meredith, R.A.M.C., died suddenly at Wiesbaden on December 6th, aged 45. He was the eldest son of the late Captain Richard Meredith, 6th Foot (Warwickshire Regiment). He was educated at the Catholic University, Dublin, where he graduated M.B., Ch.B., and B.A.O. in 1904; he had taken the B.A.M. in the previous year. After filling the post of resident medical officer of the Government Lock Hospital, Dublin, he entered the army as lieutenant on January 31st, 1905, and became major on October 15th, 1915. He served throughout the recent great war.

### Medical News.

MEMBERS of the British Medical Association are reminded that subscriptions fall due on January 1st in each year, and that if each member who receives an application for his or her subscription from the Head Office will send the amount to the Financial Secretary within the first week of the New Year the work of the office will be very considerably lightened. Members are also reminded of the claims of charity, to which reference is made elsewhere. The amounts are altogether of those who administer medical benevolence and the insufficient to meet the appeals that are received, and the British Medical Association Charities Fund was formed in order to assist. Subscriptions or donations are urgently needed, and every member of the Association is asked to add to his next payment a sum for the credit of the B.M.A. Charities Fund.

DR. RUSSELL J. RYNNOLDS, physician in charge of the Department of Radiology and Electro-Therapeutics at Charing Cross Hospital, who had been engaged for several years in the production of rapid serial skiagrams of the internal organs of the human body in motion on a cinematograph film, submitted a thesis on this subject in September, 1925, for the D.M.R.E. of the University of Cambridge, and received that diploma in March, 1926. He has since continued his experiments, and intends to read a paper on this work before the Röntgen Society on January 11th next. From paragraphs published this week in the newspapers it appears that experiments along similar lines have been in progress in the Anatomical Department at University College, London, and that a demonstration of them will shortly be given in London.

WE mentioned a few weeks ago that Dr. Lily Baker had been appointed to the honorary staff of the Bristol Royal Infirmary in charge of the ante-natal department. This is believed to be the first occasion on which a woman has been made a member of the full staff of a teaching hospital in the British Isles, except in connexion with the Royal Free Hospital, London. Other medical women connected with the Royal Infirmary have decided to entertain Dr. Lily Baker at dinner in order to afford her some public recognition of the distinction she has won. The department clinic under the general direction of the late Dr. W. C. Swayne, the professor of obstetrics, was responsible for the incidence of difficult results have been most satisfactory, the incidence of difficult and dangerous cases in the obstetric department of Miss by almost 50 per cent. The dinner will take place in Bristol on Friday, February 4th, 1927, under the chairmanship of Miss Francis G. Robinson, and among those who have promised to attend are Lady Fairfield, and Sir Ewen J. Maclean of D.Sc., Dr. Letitia Fairfield, and Sir Ewen J. Maclean of Cardiff. Tickets (price 10s. 6d. exclusive of wine), can be obtained from Miss F. G. Robinson, "The Towers," Sneyd Park, Bristol. It is hoped that many persons outside the medical profession who are interested in the higher education of, and professional careers for, women will attend.

THE Post-Graduate Hostel opens its new session at the Imperial Hotel, Russell Square, W.C.1, on Tuesday, January 4th, 1927, at 9 p.m., when Dr. Charles E. Goddard will give an address entitled "Lord Lister: by one who knew him." On Thursday, January 6th, at the same hour, Mr. Philip Turner will discuss imperfect descent of the testis. Dinner at 8 p.m. (5s.) and coffee and biscuits can be obtained at 10 p.m. (6d.). All medical practitioners are welcome. Ladies and friends of medical men are also invited to Dr. Goddard's address on January 4th.

THE Fellowship of Medicine announces that the Prince of Wales's General Hospital will hold an intensive course from January 10th to 22nd, 1927, in general medicine, surgery, and the specialties. The daily sessions from 10.30 a.m. to 5.30 p.m. will include demonstrations, operations, general hospital clinics, clinical lectures, and laboratory methods. The formal lectures at 4.30 p.m. are open to members of the Fellowship. Beginning also on January 10th there will be a two weeks' course in diseases of children at the Royal Free Hospital, from January 11th to February 5th, a series of lecture demonstrations on psychological medicine will be given on Tuesdays and Saturdays, at 11 a.m. The National Hospital for Diseases of the Heart will hold a course in cardiology from January 17th to 29th, limited to an entry of 20. For courses in obstetrics, Queen Charlotte's Hospital and the City of London Maternity Hospital personal application must be made to the Fellowship, which can also make arrangements for the appointing of clinical assistants at the Samaritan Hospital for Women. On January 27th the series of lectures arranged by the Fellowship on emergencies in medicine and surgery will be resumed. Clinical demonstrations in surgery and ophthalmology will start in January. Copies of all syllabuses of the special courses, the programme of the general course of work, and the *Post-Graduate Medical Journal* can be obtained from the Secretary of the Fellowship, 1, Wimpole Street, W.1.

DR. GEORGE JONES, lecturer on forensic medicine and hygiene, London Hospital Medical School, and Dr. G. O. Taylor, M.O.H. Berkshire, have been elected life Fellows, and Dr. R. K. Brown, M.O.H. Bermondsey, Dr. W. A. Daley, M.O.H. Hull, Dr. F. N. Kay Menzies, M.O.H. to the London County Council, and Dr. G. C. Hancock, a medical officer of the Ministry of Health, have been elected Fellows of the Royal Sanitary Institute.

THE National Temperance League has removed to 33, Bedford Place, Russell Square, W.C.1.

THE Minister of Health has issued a circular (No. 751) giving the dates on which the amended regulations, 1925, with reference to preservatives in food will come into operation. Arrangements are being made for the printing of the principal regulations as amended, and copies will be obtainable in due course through any bookseller, or direct from H.M. Stationery Office.

THE Lead Paint (Protection against Poisoning) Act, 1926, which aims at preventing lead poisoning in the painting of buildings, will come into force on January 1st, 1927. On and after that date every medical practitioner attending on, or called in to visit, a patient whom he believes to be suffering from lead poisoning contracted in or in connexion with the work of painting buildings, is required to send to the Chief Inspector of Factories, at the Home Office, London, S.W.1, a notice stating the name and full postal address of the patient. He is entitled, in respect of every such notice, to a fee of 2s. 6d. Any medical practitioner failing to send such notice is liable to a fine not exceeding 40s.

DR. FROMENT, the well known neurologist of Lyons and joint author of a work on hysteria with Dr. Babinski, was recently stabbed in the lung by one of his patients during a visit to the hospital and lies in a precarious condition.

THE restrictions imposed on the movements of the cadets and staff of the Royal Military Academy, owing to the occurrence there of cases of poliomyelitis, were withdrawn on December 13th; but all public entertainments in Woolwich were placed out of bounds for the remainder of the term, and the careful medical inspection of the cadets, already described, was maintained. The restrictions on the movements of the cadets and staff of the Royal Military College, Sandhurst, which had been imposed by the War Office owing to the occurrence of cases of poliomyelitis at Camberley, were withdrawn on December 11th, but the village of Camberley remained out of bounds until the end of term. Owing to the occurrence of a case of infantile paralysis in the family of one of the staff the restrictions had to be reimposed. The term has, however, now come to an end at both institutions and the cadets have dispersed to their homes.

UNDER the will of the residue of his real and personal estate, amounting to between £80,000 and £100,000, is left to the Lord Mayor and Corporation of London for distribution among such hospitals in the administrative County of London as they may select.

THE German Museum of Hygiene at Dresden has recently been made the seat of an Academy of Hygiene under the direction of Professor Weisbach.

PROFESSOR FERDINAND SAUERBRUCH of Munich has succeeded Professor Otto Hildebrand in the chair of surgery at Berlin University, and Professor Stepp has succeeded Professor Minkowski as director of the medical clinic at Breslau.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9361, 9362, 9363, and 9364** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### TRANSLUCENT TISSUES.

MR. STANLEY F. ---  
Institute, Sek  
Moore's Inqui

Spalteholz consists of injection of the vessels, followed by thorough dehydration, bleaching, and clearing by benzol and oil of winter green, and finally, mounting in this oil, glycerin, or liquid paraffin. It appears, therefore, that the method is scarcely applicable to the cornea of the living human eye.

#### SUNLIGHT CLINICS.

A CORRESPONDENT who is interested in the establishment of a sunlight clinic and children's hospital asks for advice as to the best type of lamp. Opinions, as he has found, differ widely, and we cannot profess to speak with authority, but we are advised that for general artificial sunlight baths the carbon arc type is the more efficient, inasmuch as it gives off a larger amount of rays. It compares unfavourably with the mercury vapour lamp as regards running expense, and also from the point of view of attention, the carbons requiring constant care. Also it is not suitable for local treatment, whilst the mercury vapour lamp is. The firm of W. E. Schall, 75, New Cavendish Street, London, W.1, has issued a bulletin (No. 1002) on ultra-violet therapy which would perhaps prove useful in making a choice; apart from illustrations and particulars as to cost, etc., there a few pages in which the theory and various points as to the different lamps are discussed.

#### INCOME TAX.

##### Assessment of Practice: Cash Basis.

"A. M. M." succeeded to a practice on September 1st, 1924, and for the year to April 5th, 1926, he was assessed on the average of two years and five months of his predecessor's earnings *plus* the earnings of himself for the seven months to March 31st, 1925—both periods being dealt with on the cash basis. The inspector has now objected to accepting the accounts for the following year (to March 31st, 1926) on a cash basis, and apparently intends to claim an adjustment, for the purpose of the assessment for 1926-27, which will cover the original seven months' account. Is this justified?

\* \* In our opinion it is justified, at any rate for the purpose of the 1926-27 assessment. It is necessary for "A. M. M." to bear in mind that as his predecessor's collection of cash for his own services is not reflected in the amount of the profits declared for the seven months to March 31st, 1925, that amount is less than the full earnings of the practice to include the value of debts being placed on the books. There was, so far as we are aware, no such factor in the case of "C. W. S.," referred to by our correspondent. The principle involved is fairly plain. A practitioner is liable on the full earnings of the practice, whether received in cash or not; where, taking one year with another, the cash receipts fairly reflect the gross earnings, then there is no reason why troublesome and difficult estimates as to the probable value of outstanding debts should be necessary. But when the fundamental condition fails the cash basis cannot properly be insisted upon—especially as a practitioner ceases to be liable on his receipts as soon as he retires from the practice.

#### Motor Car Transactions.

"L. S. G." bought a 11.9 h.p. X car in December, 1922, for £340 (present-day price £275) and sold it in December, 1926, for £90, buying a 14-h.p. car of similar make for £295. What allowances are due?

\* \* (1) Depreciation allowance for 1925-26 at 20 per cent. on, say, £200—that is, £40; for 1926-27 on £200-£40=£160—that is, £32; for 1927-28, £295 at 20 per cent.—that is, £59. (2) Obsolescence allowance to be deducted in computing the amount of the profits for 1926-£275, less £90=£185, less depreciation allowances on car displaced—that is, £72—that is, £113.

#### Assessment of Garage.

"H. K." has rented a piece of land on a seven years' agreement for £3 3s. per annum and erected thereon a garage at a cost of £75. The local authorities' permission was granted as for a temporary structure only and must be renewed annually. Is the property assessable to tax on the annual letting value, or merely on the amount of the rent?

\* \* In our view on the full letting value, assuming as we do that the structure is built into or rests directly upon the soil. The rental value placed upon it, however—namely, £18—seems high, as compared with the cost and the rent paid, but we have, of course, no means of judging the local demand for garage accommodation.

### LETTERS, NOTES, ETC.

#### MINERS' SHORTER HOURS.

DR. J. M. MACPHAIL (Middlesbrough) writes: Dr. Harbour Stephens's conclusions (November 13th, p. 905) make one think, be his statistics right or wrong. In the industrial North the men feel that with modern speeding-up men of over 50 years are not likely to be much in demand. It has been a pleasing theory for many years amongst those who do not overwork that "work never kills, but worry." Yet a good worry may even keep people alive. I have seen many deaths due to hard work and but few to worry.

#### NOMOGRAPH FOR THE DUBOIS FORMULA.

DR. JAMES KERR (Colinton) writes: Attention has been called by Dr. W. M. Feldman to omission of his name or any reference in connexion with a nomograph used on page 97 of the first issue of my recent book on *The Fundamentals of School Health*. This was a pure accident, due to transfer of the figure from the chapter on "statistics" to that on "nutrition." In a work where there are some thousands of references some errors of omission or commission were almost bound to occur. In this case the omission was dropping of the reference (*Lancet*, 1922, i, 273).

\* \* A review of Dr. James Kerr's large and important work was published last week (p. 1184).

#### VERMINOUS HOSPITALS.

MR. A. J. --- the course  
of a ne  
his art  
November 27th, refers to verminous hospitals of a bygone age, and states that "to-day we know nothing like them," citing as the last recorded example a "buggy" hospital in South Africa during the war in 1900. For many nights in August and September, 1918, when in No. II lazaret in Spandau, near Berlin, as a wounded prisoner of war, my sleep was disturbed and prevented by bed-bugs. I caught, identified, and destroyed many and displayed them to the German authorities, whose invariable reply was a shrug of the shoulders, and by whom no action whatever was taken. Later, at Beeskow-in-der-Mark, Brandenburg, I found the beds infested by fleas.

#### AN ADVERTISEMENT AGENT.

WE are informed by Dr. Kerr, M.O.H. Newcastle-on-Tyne, that a person representing himself to be an agent for "Valdar's Medical Blue Book" (177-8, Fleet Street) has recently called upon the manageress of a nursing home in Newcastle, stating that he had a list of nursing homes divided into "good" and "bad," and inviting an advertisement of the home in the "Blue Book." He appears to have stated that the classified list had been supplied by the medical officer of health, but Dr. Kerr informs us that he did not supply it. There seems some reason to believe that an agent of the book has been canvassing in London, and it is possible that he may have extended his activities to other towns. The Headquarter offices of the British Medical Association know nothing of the project.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments are found at pages 35, 38, 39, and columns; and advertisements as to and locumtenencies at pages 36 and 37. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 260.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 1. The Etiology of Achondroplasia.

C. GLAUME (*La Pédatrie*, April 1st, 1926, p. 359) reports a case of achondroplasia in a boy, aged 2½ years, who had been under observation since he was 13 months of age; there was no prenatal history in either parent, who both seemed healthy. The mother had had eight full-term pregnancies and two abortions at six months. The patient was born at term after a labour complicated by the size of the head and by hydramnios; the achondroplasia was noticed at birth. The child's head increased in size for a few months until he was treated with mercury, when it diminished. The hydrocephalus was still present to a moderate degree at the age of 2½ years. The superficial lymph glands were palpable. The Wassermann reactions in both parents were strongly positive and in the patient weakly positive. The chief interest of the case lies in its syphilitic origin, and Glaume thinks that insufficient attention has been paid to syphilis in the past in considering the origin of achondroplasia, although other toxic infective factors, such as tuberculosis and alcoholism, may also have an effect on the amniotic sac and fluid where during the three to six weeks of development, as shown recently by Mink Janssen, a retardation of development or a sudden increase of fluid compresses or rolls up the embryo. This causes local or general ischaemias the effects of which are most marked on those tissues which are in the process of most active development—namely, the cartilage bones. In Glaume's experience hydramnios is nearly always syphilitic, as was also the hydrocephalus in this particular case.

### 2. B. bronchisepticus Infection simulating Pertussis.

J. HOWARD BROWN (*Bull. Johns Hopkins Hosp.*, February, 1926, p. 147) records the case of a girl, aged 5 years, who had been in the habit of fondling a rabbit which had slight nasal discharge and was sneezing frequently. Ten days after she had been separated from the animal she developed a paroxysmal cough accompanied by a well defined whoop. These symptoms persisted for about a month and then gradually subsided. Examination of throat swabs did not show *B. pertussis* but *B. bronchisepticus*, which was also isolated from the nares of the rabbit. Only one previous example of *B. bronchisepticus* infection in man has been recorded. The case, which was reported by McGowan, was one of very irritating chronic nasal discharge in a man who had been constantly handling rabbits and guinea-pigs in the laboratory. Brown, however, is of opinion that the close association of children with pet animals and the wide prevalence of *B. bronchisepticus* infection among these animals indicate that human infection with this organism may be commoner than is recognized. He suggests that in many supposed cases of pertussis the patient is needlessly quarantined, and that if cases of *B. bronchisepticus* infection were correctly diagnosed there would be fewer cases of pertussis without a history of exposure to other cases.

### 3. Perforation of the Lung and Mediastinal Hernia in Artificial Pneumothorax.

G. SAYAGO (*La Med. Ibera*, February 13th, 1926, p. 185), who reports two illustrative cases, states that the mechanism of perforation of the lung in artificial pneumothorax may be either exogenous or endogenous. In the first case an adhesion becomes torn off at the point of its insertion into the lung, and in the second case the lung substance ruptures at the site of a pneumonic patch or a cavity. Clinically a distinction may be made between perforation occurring in cases already complicated by effusion and those occurring in cases with a healthy pleura. The former are the most frequent, and in such cases the perforation is due to ulceration of the lung substance. When the perforation occurs without any pre-existing pulmonary complications the exogenous mechanism is responsible. In these circumstances the rupture is attributable to an effort on the part of the patient, or more commonly to an excess of intrapleural tension caused by insufflation of large quantities of gas. Both the cases recorded by Sayago ended fatally—one with symptoms of shock due to a valvular perforation, and the other as the result of an extensive empyema. In the first case the perforation was attributable to a too early increase of intrapleural pressure, and in the second case to physical effort. Perforation of the lung, according to almost all authorities, is usually fatal, and if it was not so uncommon

would constitute a serious objection to artificial pneumothorax. According to Forlanini it occurs in 5.7 per cent. of all artificial pneumothorax cases. Bernard's estimate is 4.6 per cent., and Dumarest's 5 per cent. Only a few cases, such as three reported by Reventós, have ended in recovery. The treatment should be symptomatic at first and consist in evacuation of the fluid, followed in some cases by pleural lavage. In other cases treatment should be confined to tonics or sedatives, while those in which empyema has developed require pleurotomy. Subsequent treatment consists in thoracoplasty. Mediastinal hernia, which was first described by Stielmann and Rosenblatt in 1919, occurs in 15 per cent. of all cases of artificial pneumothorax. Its frequency is greater in women than in men. Except in a case observed by Sayago all have occurred on the right side without there being any obvious reason to explain this. All the cases which Sayago has seen have been in patients below the age of 25 years. Hernia usually occurs with a low intrapleural pressure and with little or no deviation of the mediastinum, which shows that its occurrence requires anatomical rather than mechanical factors. The symptoms of mediastinal hernia are scanty, and the condition is usually only discoverable by radiological examination. In some cases there is slight dyspnoea on exertion and a sense of oppression in the infraclavicular fossa on the side opposite to the treated lung, and occasionally a troublesome cough. As regards treatment, in most cases it is sufficient to prolong the interval between the refills or to reduce slightly the intrapleural pressure.

### 4. Enlargement of the Spleen in Measles.

A. BLEYER (*Amer. Journ. Dis. Child.*, January, 1926, p. 26) found that enlargement of the spleen occurred in a majority of two independent groups of cases of measles seen during three successive winters in St. Louis, and numbering altogether almost 400 persons. The enlargement of the spleen coincided with the eruptive stage, being most frequent and marked on the third and fourth days of the rash. Contrary to what might have been expected, the severity of the attack did not make the incidence of splenic enlargement higher than in milder cases.

## Surgery.

### 5. Treatment of Recurrent Dislocation of the Shoulder.

E. KÖNIG (*Zentralbl. f. Chir.*, May 8th, 1926, p. 1174) claims that Kirschner, in 1911, first introduced the method of attaching the humeral head to the acromion and clavicle by the extra-articular transplantation of strips of fascia. König states that since that date ten operations for this condition have been performed at Kirschner's clinic and that no complication occurred. The wounds healed by primary union, and in all cases there was free mobility of the joint four or five weeks after the operation. Of these 10 cases, 7 were examined from four to fifteen years after the operation. Recently 3 other patients had been operated upon and were free from recurrence, but among the 7 earlier cases recurrence followed in one. Two patients, one of whom was an epileptic, died six months after the operation without there having been recurrence. The other 4 patients remained cured after several years, 3 of them after twelve to fifteen years. Kirschner has modified his technique by cutting the fascial strips as long as possible in order to permit free movement in all directions. After operation he fixes the arm for fourteen days at an angle of 90 degrees' abduction from the chest wall, and with the elbow also flexed at this angle.

### 6. Trauma as a Cause of Malignant Growth.

J. EWING (*Amer. Journ. Surg.*, February, 1926, p. 30) criticizes the prevailing tendency to attribute the onset of malignancy to some trauma, single or repeated, and refers particularly to the problems associated with compensation claims of this kind in various industries. He mentions several cases in which the suspicion of a traumatic etiology of a malignant growth was removed by critical examination of the history and of the patient; he also gives reasons why modern conditions in industry do not for the development of malignant disease can be accepted as the cause of a tumour special care must be taken to establish the authenticity and sufficient severity

of the injury. It must be shown also that the part wounded was previously free from malignant involvement and was identical with the origin of the tumour. Again, the structure of the new growth may preclude a traumatic origin; such forms as dermoid cysts, mixed tumours of the salivary glands, neurosarcoma, and endothelioma of the dura mater are known to arise from congenital disturbances and cannot well be attributed to injury. There must be a proper time interval between the occurrence of the injury and the appearance of the tumour, depending on its nature, and it must be remembered that a part already affected with undetected malignant disease is more easily and obviously injured than healthy tissue. The author mentions two cases in which a definite injury was shown to give rise gradually to malignant disease. In the first case a healthy man injured his knee-cap; the haemorrhage and swelling never subsided, and in the end a very cellular spindle-celled periosteal sarcoma developed. The second case was that of a boy struck on the inner side of the thigh; an x-ray examination showed slight damage to the periosteum and an erosion of the shaft of the femur. A later x-ray examination justified a diagnosis of osteogenic sarcoma. Ewing states that a period of three years has sometimes been considered the longest interval which may elapse before a trauma can be rejected as the possible cause of malignant growth, but no uniform rule is possible. He adds that experimental efforts to produce cancer by various forms of single trauma have been unsuccessful, and he concludes that more careful investigation is necessary before it can be assumed that malignant disease is not uncommonly referable to injury.

#### 7. Tumours Round the Knee-Joint.

R. GOUVERNEUR and A. LEBLANC (*Bull. et Mém. Soc. Nat. de Chir.*, May 8th, 1926, p. 454) record three cases of tumours arising in the neighbourhood of the knee-joint in young subjects between 20 and 27 years of age. They were found on the outer aspect of the knee-joint near the superior tibio-fibular articulation and were ovoid and hard. They did not appear to communicate with the joint itself as certain cysts arising in the popliteal space are sometimes found to do. At the operation also no pedicle or communication with the joint was found. They appeared to arise from the fibrous tissue in the outer aspect of the knee where this is particularly thick and well developed. The authors state that an interesting feature of these tumours is their tendency to recur after removal, without any evidence of malignancy. In one case after removal a thickening in the same spot was noticed three months later; a second operation removed a similar tumour and the patient appeared to be cured six months later. Histological examination showed that these growths were cystic tumours, at first of a fibrous nature and later undergoing myxomatous degeneration.

#### 8. Prostatic Calculi.

M. MAISONNET (*Journ. d'Urol.*, April, 1926, p. 350) records two cases of calculi found in the prostate; he thinks that such calculi do not arise from the so-called prostatic concretions. In one case the patient gave a history of renal colic twelve years previously, and this may possibly have been the starting-point of a renal calculus becoming lodged in the prostate. The second case appeared to be undoubtedly primary, as the calculus developed in the prostate itself. Neither prostate showed any evidence of inflammatory trouble: one was a typical adenoma, the other showed signs of multiple cystic formation. Both patients came for treatment on account of trouble on micturition, and radiographs revealed the presence of calculi. Removal by the urethra appeared impossible, and Maissonnet thinks that removal by the natural passages will be only exceptionally feasible. In both cases the calculi were removed by suprapubic prostatectomy; the operation was quite easy and the results have been most satisfactory. Radiographical illustrations are given of the prostatic calculi before and after removal.

#### 9. An Anomalous Position of the Appendix.

H. KÖHLER (*Zentralbl. f. Chir.*, May 1st, 1926, p. 1115), who records a case of ectopic appendix, states that in anatomical textbooks four positions only for the appendix are described—the pelvic, superior ileo-caecal, inferior ileo-caecal, and retrocaecal. The author's patient was a girl, aged 15, who had all the usual symptoms of acute appendicitis. An operation was performed, and the appendix, which had a short mesentery, was found to spring from the antero-inferior surface of the ileum, 2 cm. from the ileo-caecal valve. On opening the peritoneum the appendix could not be seen or felt, being deeply situated behind the caecum. It was densely adherent to all the surrounding structures, so that it was only after it had been freed from these that its anomalous origin was discovered.

## Therapeutics.

### 10. Local Vaccine Therapy in Chronic Urethritis.

O. MICHAELIS (*Brucelles Méd.*, May 2nd, 1926, p. 789) states that the majority of cases of chronic gonorrhoeal urethritis are due to a mixed infection of *B. coli*, staphylococci, and other organisms, with or without gonococci. Urethral filaments are usually due to infection of Littre's glands. When urethroscopic examination reveals a pinhead bulbous appearance of the orifices of these glands the author removes the lamp, leaving the urethroscope *in situ*; through the tube he introduces a wooden probe, 35 cm. long, armed with cotton-wool. The orifices are first rubbed thoroughly with a mixture of equal parts of tincture of iodine and alcohol. After one or more such applications at intervals of two or three days the author gives an intraurethral injection of Bruschettini's anti-pyogenic and antigenococcal vaccines, rubbed in with the wooden probe. After five or six applications the cotton-wool ceases to be blood-stained and the urethral filaments become less purulent, but the subsequent mucous secretion persists until twenty or thirty applications have been made. The author agrees with Bruschettini that the activity of the anti-pyogenic vaccine is not due to the small quantity of ether added as a preservative; that the antigenococcal vaccine has a less definite effect—probably by reason of the mixed infections in chronic cases; and that these vaccines are too irritant in acute and subacute gonorrhoea. The author claims that by this method scarring, infiltration, and stricture are prevented. As there can be little doubt that gleet is contagious, it is necessary to examine the mucous secretion frequently for gonococci. These may be found present in a smear after eight or even ten negative examinations. Local antipyogenic vaccine therapy properly applied may be very efficacious in these chronic cases. It is probable that the gonococci disappear as the catarrhal congestion of the mucosa clears up.

### 11. Trinitrine in Arterial Hypertension.

C. MATTEI and J. DIAS-CAVARRI (*Bull. Soc. de Thér.*, April 14th, 1926, p. 107) carried out a series of observations with the oscillometric sphygmomanometer to determine the action of trinitrine in arterial hypertension. The results were as follows. Trinitrine lowered the maximal pressure by 2 to 4 cm. in three out of nine patients. A short stage of hypertension generally preceded this fall, which was most pronounced ten to twenty minutes after ingestion of the drug. The minimal pressure remained unchanged. In six out of nine cases the oscillometric index showed a remarkable increase with acceleration of the pulse, exactly as occurs after administration of sodium nitrite. The increase in the oscillometric index reached its height seven to twenty minutes after the trinitrine had been taken. Both the index and the pulse returned to normal in two hours' time. All these changes were very transient and disappeared on the day after the drug had been discontinued. The authors conclude that trinitrine is a drug of which the hypotensive effects are unreliable and transient. Moreover, trinitrine, like sodium nitrite, presents the disadvantage of increasing the oscillometric index without appreciably lowering the arterial tension. These drawbacks prevent trinitrine ranking as a good hypotensive remedy.

### 12. Non-specific Protein Therapy.

J. JARCHO (*Med. Journ. and Record*, February 17th, 1926, p. 237) has been using non-specific protein therapy in the treatment of pelvic infections with considerable benefit. He disagrees with the observations by some investigators that the rapid febrile reaction following the injection of milk is the healing factor and that the injections are followed by a marked leucocytosis. He states that these severe reactions are due to the presence of micro-organisms in the milk, and they can be greatly reduced by the use of pasteurized certified milk, or milk in the form of "aolan," a proprietary preparation which he used in his cases. Milk does not cause even a perceptible local reaction when the fat has been removed by centrifugalization. His method of administration was to inject 5 c.cm. of milk, or a smaller quantity in very sick patients, into the gluteal region; this injection was repeated at intervals of three to five days for a number of injections. Jarcho's cases required from three to eight injections, the third and subsequent doses being 10 c.cm. Following the injection there was a slight reaction consisting of malaise to a greater or lesser extent and pain in the abdomen, but only in the very sick was there a marked rise in temperature. The leucocytosis always increased by 2,000 to 5,000 per c.mm. within six hours after the initial injection and gradually disappeared within twenty-four hours; it tended to decrease after each injection. The majority of Jarcho's patients showed a remarkable improvement after the reaction of

the first injection; he therefore strongly recommends the use of this treatment in cases of pelvic infection, in conjunction with dieting, fresh air, and other supplementary measures.

### 13. Treatment of Varicose Ulcers.

R. H. DAVIS (*Arch. of Derm. and Syph.*, April, 1926, p. 519), during the last two and a half years, has treated 55 cases of varicose ulcers by the following preparation: borie acid 63 grams, potassium hydroxide (stick) 28 grams, water 200 c.c.m. The procedure is as follows: any crusts present are removed from the base of the ulcer, and the solution, diluted one-half with water, is mopped gently on the ulcer. A variable amount of pain ensues, usually not lasting more than fifteen to twenty minutes. Simple Lassar's paste (zinc oxide, starch, and vaseline) is then applied twice daily. If possible the application should be made three times a week at least. In the majority of cases so treated a cure was effected in from a few weeks to four months.

### 14. Mercurochrome in Acute Infections of the Central Nervous System.

W. H. HENGSTLER (*Minerata Med.*, May, 1926, p. 240) reports three cases of infectious meningitis, following middle-ear infection, which were treated by the injection of a 1 per cent. solution of mercurochrome into the spinal canal. Death followed in each case, and the author doubts whether the drug has any value in these diseases. Moreover, using intravenous injections of 5 mg. of mercurochrome for each kilogram of body weight, they have observed no satisfactory results in acute epidemic encephalitis, though they report that J. W. Vischer obtained marked improvement in two cases using a rather smaller dose. Hengstler therefore concludes that, although mercurochrome appears to have been so valuable in septic infections elsewhere, it has no beneficial action on infection of the central nervous system.

## Dermatology.

### 15. Cutaneous Myomata.

O. ANGELELLI (*Il Policlinico*, February 15th, 1926, p. 69) reports a case of cutaneous myoma occurring on the foot of a child aged 3, and discusses the condition. After referring to various records of similar cases he deals with the etiology; of the various hypotheses suggested he prefers the vascular theory. These tumours, which are usually small but may reach the size of a Tangerine orange, may be solitary or multiple. They are generally tender on pressure and painful at times, but may be quite painless; they are always hard in consistence, never ulcerate, and are attached to the skin, which is usually unaffected. Although more often seen in adults, they may appear at any age; they are slow in developing and persist for many years. They have to be distinguished from tuberculous or syphilitic lesions, from neuromata, mycosis fungoides, fibroma molluscum, and retention cysts; usually there is no difficulty in diagnosis. They are made up of smooth muscle fibres and connective tissue. Drawings of the histological appearance of the tumour in the author's case are given, and a bibliography of the most important literature on the subject.

### 16. The Cholesterol Content in Skin Disease.

R. BERNHARDT and G. ZALEWSKI (*Ann. de Derm. et de Syph.*, March, 1926, p. 171) think that it is now well established that a high cholesterol blood content exists in those skin diseases which are marked by pruritus, and is absent in such conditions as psoriasis, which are not associated with pruritus. Their own investigations include over 300 cholesterol estimations made in 100 patients suffering from various dermatoses. In skin suppuration of all kinds they found high cholesterolinæmia, as also in lupus and suppurating tuberculides; in a group of conditions including lupus erythematosus, the papular forms of Boeck's sarcoid, and mycosis fungoides, usually regarded as having affinities with tuberculosis, the cholesterol content was also increased. In epithelioma it was increased; their highest figures were recorded in furunculosis. Psoriasis seemed to be about the only skin affection in which there was a manifest diminution of cholesterol. They think that the frequent occurrence of pyogenic skin affections, especially those of staphylococcal origin, may be responsible for the high cholesterolin content found in seborrhoeic eczema and in occupational dermatoses. Cholesterol cannot, the authors consider, be definitely classed as a protective substance, or as a toxin, but, since it is either formed or deposited in the suprarenal capsule, it is probable that some endocrine factor is concerned.

### 17. Primary Benign and Malignant Melanoma of the Skin.

L. MCCARTHY and L. K. McCAFFERTY (*Brit. Journ. of Derm. and Syph.*, March, 1926, p. 101) discuss the origin of the cells of pigmented naevi of epithelial and mesenchymal derivation in primary benign and malignant melanoma of the skin, also the origin and nature of the pigment. Benign melanomata (moles or pigmented naevi) are more of the nature of local developmental defects of the skin than of real tumours, but they may develop into malignant tumours, the naevocarcinomata, and all malignant tumours arising from such naevi will be naevocarcinomata and not naevosarcomata or melanocarcinomata. The so-called blue naevus is of mesenchymal origin, and the cells are identical with those of the mongolian spot, and malignant degenerations of this type of naevus result in naevosarcomata. When a naevus takes on malignant changes it rapidly enlarges, becomes red and then more deeply pigmented; with the subsequent ulceration a number of small tumours appear in the immediate neighbourhood. After remaining quiescent for years a blue naevus may suddenly take on active proliferative changes and develop into a naevosarcoma with invasion of the lymph glands and widespread metastases. A melanocarcinoma originates from normal epithelial cells which have not undergone a naevoid metaplasia, and these pigmented spots, after a slow progressive extension in all directions, eventually give rise to a malignant tumour the cells of which are identical with those found in a naevocarcinoma.

### 18. Larva Migrans.

N. MELCZER (*Dermatol. Woch.*, March 20th, 1926, p. 385) reviews the literature and reports two cases of "creeping eruption," which is caused by the larva of *Gastrophilus equi* (gadfly). Many cases have now been recorded of human patients, especially children, being attacked by these larvae, which produce a long serpentine track by tunnelling between the skin and the subcutaneous areolar tissue. In Melczer's first case, a child, during eighteen days' observation the larva burrowed from the left flank to the loin and the left gluteal region. The serpentine tunnel terminated in a depressed hyperæmic area as large as a farthing and was surrounded by an urticarial zone. This area was excised under novocain anaesthesia. In his second case, a man, aged 28, was stung at the side of a metacarpo-phalangeal joint; two days later the site became inflamed and an advancing red sinuous raised line was seen on the side of the finger, extending up to the terminal phalanx. The small black splinter-like parasite was removed with a needle and identified under the microscope. The treatment recommended by various writers includes excision, electrolysis, and the injection of 0.5 per cent. carbolic acid lotion, alcohol, ether, or chloroform. These are sometimes very painful and may give rise to necrosis and also localized scarring.

19. O. K. SCHOLL (*Dermatol. Woch.*, April 3rd, 1926, p. 467) has seen a number of cases of "creeping eruption" in Rio de Janeiro and recommends the application of chlorethyl. If this fails to destroy the larva he uses carbon dioxide snow, applied freely in order thoroughly to freeze the skin over the larva. When the parasite is in a region in which a scar will not disfigure the patient, a well planned excision is, he thinks, the most certain method.

## Obstetrics and Gynaecology.

### 20. Serological Diagnosis of Pregnancy.

H. RUNGE (*Zentralbl. f. Gynäk.*, May 15th, 1926, p. 1297) refers to the work of Hirsch and his co-workers, who have applied the interferometer to the diagnosis of pregnancy and other conditions by Abderhalden's reaction. During early pregnancy they were able to detect in this way a lysis by the blood serum of the protein in placental extracts. By similarly using as substrate extracts of myomatous, carcinomatous, and other pathological tissues they claimed to have found in the serum reactions which were of diagnostic significance. Runge has tested the value of the interferometric reaction in 150 cases, chiefly of early pregnancy. Although he found that the average destruction of placenta substrate was greater in the serum of patients from two to nine months pregnant than in that of non-gravid patients, he reports that the variations are so wide as to rob the action of diagnostic value. Thus in 28 per cent. of non-pregnant patients a positive reaction for pregnancy was given, and in 33 per cent. of late pregnancies the test was negative. Successful prophecies as to the sex of the foetus have, it is said, been made by interferometric tests of the maternal serum against substrates of testis and ovary, but Runge has not found that the test possesses any value in this connexion.

## 21. Treatment of Uncomplicated Gonorrhoea in the Female.

H. W. MARTIN (*Med. Journ. and Record*, February 17th, 1926, p. 246) considers that in order to treat successfully acute gonorrhoea in the female there must be as good drainage as possible, and frequent or semicontinuous medication to the vagina with an agent which does not react chemically with the normal and pathological secretions and be thus rendered inactive. In his opinion acriflavine meets this requirement, and although so far he has used it in only a small series of cases the results have been exceptionally good. The procedure he employs is to teach the patient first to douche the vagina, and then when she is lying on the back with the buttocks slightly raised 25 c.cm. of a 1 in 500 to 1 in 1,500 solution of acriflavine are injected into the vagina through a Day syringe, the patient retaining this position for at least half an hour. By this means, owing to the filling of the vagina, the acriflavine has ample opportunity to penetrate the walls and the mucous glands of the cervix and endocervix, but it is not precipitated, as are most silver salts, when injected. This practice, repeated twice daily by the patient and combined with general treatment, will, in most cases, rapidly relieve gonorrhoeal cervicitis and vaginitis. It has no effect on infection of Bartholin's glands and the Fallopian tubes. Protargol may be used with equal efficacy in this way, but vaginal suppositories, sprays, and painting the vagina and cervix have been found very unsatisfactory by the author.

## 22. The Second Stage of Labour.

J. B. DELEE (*Surg., Gynecol. and Obstet.*, May, 1926, p. 701), discussing the principles of the technique of the second stage of labour, considers it imperative that the accoucheur should be in personal attendance to protect against infection, injury, and complications, to relieve pain, and to safeguard the infant. Besides the observance of strict asepsis and antiseptics attention should be paid to keeping up the mother's strength and resistance to bacterial invasion, preventing loss of blood, and the avoidance of mental and physical exhaustion and injury. By allowing the head to descend slowly and without intervention, and by the judicious use of anaesthetics, the possibility of injury to the pelvic connective tissues is prevented; this affords the best guarantee against infection and later trouble. The routine use of pituitrin in this stage is condemned. A timely episiotomy may save perineal damage and relieve the foetal head from injurious pressure. DeLee regards the abolition of pain as a primary duty in the second stage, and prefers ether as the anaesthetic. He considers that too little attention is often paid to the preservation of the life and health of the child, and advocates frequent auscultation of the heart. A decrease in the heart beat to 100 or less indicates that the child is in danger and should be extracted; during its birth the eyes, lungs, navel, and intestinal canal must be protected against infection. The possibility of such complications as abruptio placentae, rupture of the uterus, eclampsia, and cardiac collapse must not be forgotten.

## Pathology.

## 23. Estimation of the Curative Value of Antidiphtherial Toxin.

T. MADSEN and S. SCHMIDT (*Ann. de l'Inst. Pasteur*, April, 1926, p. 300), using Ramon's flocculation test, have studied the problem why there is no absolute parallelism between the antitoxin titre of a serum and its curative power. They find that the time taken for a precipitate to form in a diphtherial toxin-antitoxin mixture varies according to the source of the antitoxin. Thus the serum from one horse may combine *in vitro* with toxin in a small fraction of the time taken by the serum from another horse, even though the antitoxin titres of the two serums are the same. A similar difference in the rate of neutralization can be demonstrated *in vivo*; one serum injected intravenously into a rabbit previously inoculated with toxin will completely neutralize the toxin in a few minutes, whereas another serum may take as long as fifteen hours. The rate of neutralization, like the rate of flocculation, is independent of the antitoxin titre of the serum; it depends on the animal furnishing the serum, and in any one animal it remains practically constant throughout the course of immunization. It can also be shown that there is a close relation between the rate of combination of a serum—or its "avidity," as the authors call it—and its curative power. In one experiment they found that a serum containing 250 antitoxin units and taking seventy-five minutes to flocculate was able to neutralize toxin immediately—tested by the intravenous injection of rabbits; of this serum only 10 units were required to save rabbits that had been injected one hour previously with six lethal doses of toxin. Another serum containing 150 antitoxin units and taking fifteen hours

to flocculate required fourteen hours to neutralize toxin; of this serum 150 units were required to save rabbits injected with toxin. There are thus two important properties of a serum: (1) its antitoxin content, and (2) the avidity it has for toxin. It is possible that the use of serums having a high index of "avidity" may be of special value in the treatment of diphtheria.

## 24. The Function of the Appendix.

F. MOUTIER and R. FOUCHÉ (*Presse Méd.*, April 28th, 1926, p. 532), discussing the function of the appendix, deny that it is a regressive organ, since it appears only in the more advanced animals. They give evidence favouring some of its suggested functions, including the production of an external secretion, the provision of a defence against bacterial invasion, and its being an important abdominal centre of reflex nervous action. The authors suggest that evidence bearing on these possibilities should be looked for carefully in cases where the appendix has been removed, and they refer to five cases where marked obesity followed removal, four cases where menstrual disorders occurred, and four cases where constipation was the sequel. In all these cases the appendix was removed free from infection and none of the patients had suffered previously from the disorders which afterwards appeared. It is thought possible that there is some endocrine relation between the appendix, thyroid, and ovary, and possibly the pancreas also, of which evidence might be obtained by a systematic study of the disorders following appendectomy.

## 25. Haemolytic Streptococci in Milk.

J. H. BROWN, W. D. FROST, and M. SHAW (*Journ. Infect. Dis.*, May, 1926, p. 381) have made comparative studies on streptococci isolated from cases of epidemic sore throat and from certified milk. Five dairy herds were examined, and 83 strains, of which 21 gave the beta type of haemolysis, were isolated. A few strains of *Streptococcus pyogenes*, *anginosus*, and *infrequens* from various sources were included. The throat strains, which they classify under the term *Streptococcus epidemicus*, agreed closely with each other. They were roundish cocci, producing beta-haemolysis in blood agar, haemolysing rabbit blood cells in fluid suspension within two hours, killing mice inoculated intraperitoneally with 0.5 c.m. of culture in less than a day, fermenting glucose, lactose, sucrose, and salicin, but not mannite, producing in 1 per cent. glucose broth a final hydrogen-ion concentration not higher than pH 4.8, failing to hydrolyse sodium hippurate, and showing a capsule when observed under suitable conditions. The milk strains were divided into nine different groups. None of them showed a definite capsule, most of them hydrolysed sodium hippurate, and all with one exception produced a final hydrogen-ion concentration in glucose broth of pH 4.8 or over. The authors consider that none of these milk strains are pathogenic for human beings. The differentiation of the haemolytic streptococci is discussed, and, though no single method can be relied on, they regard the final hydrogen-ion concentration in glucose broth and the hydrolysis of sodium hippurate as the most constant and reliable tests for distinguishing between strains of human and bovine origin.

## 26. Pneumococcal Immunization.

S. T. WOO (*Journ. Exper. Med.*, May, 1926, p. 623) states that Robertson and Sia found that the blood of animals which are resistant to invasion with pneumococci possesses special destructive powers for these organisms; this led him to suggest that natural immunity to pneumococcal infection was dependent chiefly, if not entirely, on the pneumococcidal activity of the blood. This work has been amplified by Woo, and a greater number of virulent and avirulent strains has been used. The virulence of each strain of pneumococcus was tested by the intraperitoneal injection of three or four rabbits with varying amounts of culture, and compared with the ability of the strain to grow in a serum-leucocyte mixture prepared from normal rabbits. The results indicated a close parallelism between these two properties. A strain that was able to grow freely in the serum-leucocyte mixture after inoculation in minimal amount proved virulent when injected in minimal amount into rabbits. It was also observed that the extreme susceptibility of the young rabbit to strains of pneumococci of low virulence to adult animals was associated with an absence of pneumococcidal properties in the blood of the young rabbit. Woo concludes that in the blood of resistant animals, such as dogs and cats, there are substances capable of destroying pneumococci which are highly virulent to adult rabbits, and that in susceptible animals, such as rabbits and guinea-pigs, the diminution of susceptibility as the animals grow older is associated with an increase in the pneumococcidal action of the blood. His findings suggest that the type of defence mechanism against pneumococcus infection is the same in resistant as in susceptible animals, but that the degree to which this mechanism is developed shows a marked difference.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 27. The Action of Digitalis on Premature Ventricular Contractions.

H. L. OTTO and H. GOLD (*Arch. Intern. Med.*, April 15th, 1926, p. 562), discussing the action of digitalis in cardiac arrhythmia, state that it is well known that digitalis may produce premature ventricular contractions, a condition often associated with auricular fibrillation. The few clinical observations on the effect of digitalis on premature contractions are contradictory and unsatisfactory. These contractions may occur in hearts otherwise normal. It is known that large doses of digitalis can produce premature contractions in some patients, and the authors report a case which shows the influence of large doses on spontaneous premature contractions. A man, aged 55, had rheumatism at 43, but there was no history of vascular or other diseases in adult life. He had moderate brachial and temporal arterio-sclerosis; the heart and other viscera were normal. There was moderate hyperplasia, the systolic pressure was 190 to 200 mm., and the diastolic 90 to 100 mm. Hg. An electro-cardiogram showed basic sinus rhythm interrupted by frequent presystoles, ranging from thirteen to fifteen a minute. On the sixteenth day 19 c.cm. of the standardized tincture of digitalis was given in one dose in the morning; five hours later the systoles were regular and no premature beats occurred until the third day afterwards. Eight days after the large dose 3 grains daily of powdered digitalis leaf was given for four days, but failed to abolish the extra-systoles, although they became less frequent. For fifty-nine days digitalis was discontinued, and the premature contractions returned as on admission—four to fourteen a minute. On the ninety-second day another dose of 19 c.cm. of the standardized tincture was given; in seven hours the extra-systoles had ceased. During the next thirty-one days daily doses of 3 grains of powdered digitalis leaf were given, and the systoles were regular; on the 124th day the drug was again discontinued. The extra-systoles reappeared on the 194th day—that is, sixty-nine days after withdrawal of the drug. There was no evidence of circulatory failure; the disappearance of the extra-systoles was not accompanied by any subjective or objective evidence of improved circulation. There was no change in blood pressure, but the annoying sensation of "jumping of the heart" disappeared in the absence of extra-systoles.

### 28. A Gastro-Intestinal Type of Cerebro-spinal Meningitis.

E. ABEL and P. BRENAS (*Rev. Med. de l'Est*, February 1st, 1926, p. 95) observe that in children this disease may be of relatively insidious onset, as compared with the fulminating type that usually characterizes cerebro-spinal meningitis in adults. In this respect it may be mistaken for tuberculous meningitis. The authors describe three cases of infantile cerebro-spinal meningitis in which the children, whose ages ranged from 6 to 20 months, exhibited symptoms of acute gastro-intestinal disturbance, accompanied by slight stiffness of the neck and prominence of the fontanelles, and, in two cases, by the presence of Kernig's sign. Repeated lumbar punctures showed that there was a high degree of leucocytosis; the fluid was deep yellow and under increased pressure, and in two cases the meningococcus was isolated. In the third case no bacterial growth was obtained by swabbing the cerebro-spinal fluid or the pharynx. Two of the children made good recoveries after several lumbar punctures and the injection of antimeningococcal serum, while in the third case chronic hydrocephalus supervened.

### 29. Statistics of Laryngeal Diphtheria.

J. V. BOKAY (*Deut. med. Woch.*, February 12th, 1926, p. 267) states that 234 cases of laryngeal diphtheria underwent operation in his clinic at Budapest during the years 1915-24. Of these, 159 recovered and 75 died—a mortality of 32 per cent.; 220 underwent intubation only, with 149 recoveries, and 71 died—a mortality of 32.2 per cent. On 14 patients secondary tracheotomy was performed, with 10 recoveries and 4 deaths—a mortality of 28.5 per cent. During the same period 228 cases of laryngeal diphtheria did not undergo any operation. Of these, 210 recovered and 18 died—a mortality of 7.8 per cent.; 65 were under 2 years of age, and of these 58 recovered and 8 died—a mortality of 12 per cent. Of 162 over 2 years of age, 152 recovered and 10 died—a mortality of

6.1 per cent. Thus out of 462 cases of laryngeal diphtheria 228, or 47 per cent., escaped operation. The 18 deaths occurred in cases of descending croup or septic diphtheria, in which operation would have been of no avail. Of all the patients with laryngeal diphtheria 53 per cent. underwent operation, and 68 per cent. of the intubation cases recovered. Primary tracheotomy was not performed in any case, and secondary tracheotomy only in 6 per cent.

### 30. Tuberculous Laryngitis.

T. RUDD (*Arch. Internat. de Laryngol., Otol. et Rhinol.*, December, 1925, p. 1174) has come to the conclusion that tuberculous laryngitis is curable. Some patients may recover without local therapeutic or surgical measures by sojourning at high altitudes, with or without artificial pneumothorax or other thoracic intervention. The author has never seen a case in which tuberculous laryngitis was the only manifestation of the disease in the body. It is more often found in the interior of the larynx than at the entry; the bodies of the arytenoids and the epiglottis are rarely affected, but the interarytenoid region and the vocal cords are much more commonly involved. The author considers that these sites are determined by an acquired or hereditary lack of resistance to the infection rather than to any anatomical peculiarity. The percentage of cures is very much higher when only the vocal cords are affected than when the disease has spread to neighbouring parts such as the interarytenoid region. The most unfavourable prognosis is when there is dysphagia and when the disease has involved the whole larynx. In such cases there is danger of suffocation, and either a tracheotomy may be performed or the interior of the larynx may be curetted. For the severe pain in such advanced cases injection of alcohol into the superior laryngeal nerve just above the wing of the thyroid cartilage gives great relief. Surgical measures in less advanced cases consist in the galvanocautery, application of lactic acid, mentholated oil, anaesthetizing powders, and phototherapy—by direct sunlight where available, or by electric arc light. The author has not used x-ray treatment often. The chief indication for treatment locally is when a case of mild degree is progressing in spite of general treatment and especially where the lung condition is improving at the same time. Other indications are an irritating cough, dysphagia caused by ulceration of the glottis, laryngeal stenosis, fever due entirely to the laryngeal condition, and in some cases mental depression.

## Surgery.

### 31. Dislocation of the Carpal Bones.

F. M. CADENAT (*Bull. et Mem. Soc. Nat. de Chir.*, March 13th, 1926, p. 262) discusses the treatment of subluxation of the carpal bones; he considers that reduction is always difficult and often impossible. In five cases he could reduce the dislocation only once. If reduction cannot be performed it may be necessary to operate and either force the displaced bone into position or remove it altogether. The best approach is, he thinks, from the dorsum. A feature he has noticed in these cases has been the severe pain radiating down the median nerve into the fingers. In one patient this was very marked indeed. The pain, combined with swelling of the wrist, often enables a diagnosis of dislocation to be made. The ultimate results are often not very satisfactory. While no deformity may be left the movements of the wrist and fingers are frequently somewhat limited. Massage and movement must be steadily persisted in after these injuries.

### 32. Autogenous Blood Injections in Facial Carbuncle.

R. HINZE (*Zentralbl. f. Chir.*, April 17th, 1926, p. 987) describes three cases of facial carbuncle treated by Læwen's method—namely, the injection of the patient's own blood into the healthy tissues outside the inflammatory area. All the patients were seriously ill when admitted to hospital, and did not improve under routine treatment, including incision, application of aluminium acetate fomentations, and vaccine therapy. After the injections of their own blood every patient made a rapid recovery. A woman, aged 30, had a diffuse carbuncle of the lower lip, with pyrexia and rigors. Fomentations and vaccine treatment produced temporary improvement only. There was general cyanosis at the time that 6 c.cm.

of the patient's own blood was injected into the healthy tissues on either side of the inflammatory focus; some of the blood escaped through the incision and sinuses. Next day there was definite improvement, the sloughs separated, and on the third day the patient was discharged cured. A man, aged 60, had a carbuncle involving the entire upper lip, and for five days fomentations and vaccines were used without improvement. On the sixth day 6 c.cm. of the patient's blood was injected in the naso-labial folds on each side of the carbuncle. Next day there was a rapid improvement, and the patient's further progress was uninterrupted. A boy had a carbuncle of the upper lip; his whole face below his eyebrows was swollen. After two courses of vaccine treatment and two injections of the patient's blood on the sixth and eighth days after his admission he began to improve; on the latter day he received 14 c.cm. of blood, because at the first injection much of the blood escaped through the sinuses and the preliminary central incision. After the second injection the patient made a rapid recovery. HINZE remarks that in order to obtain the full benefit of this treatment an attempt must be made to maintain the continuity of the tissues so as to conserve the bactericidal and antitoxic action of the injected blood. In addition to the other benefits of this treatment, the cosmetic result in all these cases was excellent.

### 33. Subphrenic Abscess.

L. R. FIFIELD and R. J. MCNEILL LOVE (*Brit. Journ. of Surgery*, April, 1926, p. 683) give their conclusions based on a series of 78 consecutive cases of subphrenic abscess. Appendicitis was the cause in 30 cases, the most common variety being the right posterior intraperitoneal. Perforation of a gastric or duodenal ulcer was the origin of the abscess in 24 cases. Intraperitoneal subphrenic abscess is an end-result of acute localized peritonitis. Inflammatory exudate is poured out and after ten to fourteen days a localized abscess is present. The abscess often contains gas from a perforated viscus or is formed by *B. coli communis*. As the abscess enlarges the diaphragm is pushed upwards. An empyema may form and the lung collapse. The extraperitoneal variety is an example of cellulitis terminating in suppuration. The abscess may rupture into a neighbouring viscus; a gastric or duodenal fistula is distinctly uncommon. The diagnosis may be very difficult. The history is often suggestive where an infective focus in the abdomen has been dealt with; the patient temporarily improves, after which signs of toxæmia supervene. A local swelling of the ribs may be seen and immobility of the chest. The liver may be displaced downwards. Effusion or other signs in the chest may be found, and gas may be discovered on percussion. Radiographical examination is most valuable and shows elevation or immobility of the diaphragm, while the final resort is the exploring needle. The treatment is prophylactic first and drainage of a septic focus. When pus is found the rib below the needle is excised, the diaphragm incised, and a tube inserted. Posterior drainage should be arranged when possible. The mortality was 50 per cent.

### 34. Surgical Treatment of Cholelithiasis.

H. HABERER (*Deut. Zeit. f. Chir.*, March, 1926, p. 1) has performed 565 operations on the gall bladder and bile ducts, which he classifies as follows: cholecystectomies, with or without drainage of the bile ducts, 510; cholecystostomies, 18; cholecystenterostomies, 17; choledochoduodenostomies, 8; cholecystodynes, 11; and fistula of the bile duct, 1. The total mortality was 6 per cent. His conclusions are as follows: (1) Cholelithiasis should be operated on early and in young persons, as was decided by the German Surgical Congress in 1923. (2) During the acute stage operations should be limited to cases of emergency, as the prognosis is worse than when the operation is performed in an interval between attacks. (3) The operative mortality must be reduced by careful technique and attention to anatomical details on the one hand and by choosing the right time for operation on the other. (4) The operation of choice is cholecystectomy. (5) Cholecystotomy cannot be entirely dispensed with, but is often required when removal of the gall bladder appears to be too dangerous a procedure. (6) Cholecystodynes should not be condemned as an operation, although the indications for it are few; it is only permissible when gall stones are discovered in a visibly and palpably normal gall bladder during an operation for some other cause, such as gastric or duodenal ulcer. (7) Obstruction of the common bile duct should be operated on without delay, so as to avoid such severe complications as liver abscess, cholangitis, pancreatitis, and anaemia. (8) The unsatisfactory results of operation, such as reappearance of pain, are to be attributed least of all to adhesions, but rather to recurrence of gall stones in the bile ducts or to a persistence of slight cholangitis.

102 B

## Therapeutics.

### 35. Administration of Luminal.

H. A. PATTERSON, LE G. A. DAMON, and P. LEVI (*Journ. Nerv. and Mental Dis.*, May, 1926, p. 446), from a comparative study of various methods (oral, subcutaneous, intravenous, and intraspinal) of the administration of luminal in epilepsy, found that no ill effects were produced by any method and that no tolerance for the drug developed. In approximately 300 patients to whom 1½-grain tablets were given by the mouth each evening a reduction of 45 per cent. in the number of seizures was noted, the severe attacks being reduced 60 per cent. while the mild ones were diminished only 22 per cent. This more favourable influence upon the severe than upon the mild attacks is in accord with the generally accepted opinion, pointing to the fact that luminal, by acting chiefly upon the motor centres, is more efficient in those cases in which the motor element predominates. Since untoward symptoms follow sudden cessation of the drug a gradual reduction in dosage should be adopted when its discontinuance is indicated. In the subcutaneous administration luminal sodium in doses of from 5 to 15 grains was used for serial seizures and status epilepticus in which oral administration was difficult and a more rapid result was needed. About 50 per cent. of cases of serial seizures responded favourably, but only a small percentage of benefit occurred in status epilepticus. In the intravenous method the initial dose was 2 grains, increasing by 1 grain at two-day intervals up to a maximum of 5 grains. In seventeen cases treated with over a hundred injections no ill effects arose, and striking results were obtained in three cases of status epilepticus. The intraspinal method seemed to be of use in those refractory cases in which treatment by the other methods has failed. The period required for the appearance of therapeutic effects in each of the four methods was: orally, one to two hours; subcutaneously, fifteen to thirty minutes; intravenously, almost immediately; intraspinally, half an hour or longer. The authors conclude that the oral method, when giving satisfactory results, is preferable on account of its simplicity and the fact that it can be continued over long periods; while the subcutaneous method is preferable in serial seizures, the intravenous in status epilepticus, and the intraspinal for rendering refractory cases more amenable to other forms of treatment.

### 36. Mercury in the Treatment of Syphilis.

L. SPIEGEL (*Med. Journ. and Record*, April 21st, 1926, p. 510), finds that in the treatment of syphilis a combination of salvarsan and mercury gives the best results when both drugs are administered intravenously. He recognizes the value of bismuth, but thinks that since it has not the spirochaetocidal power of mercury or salvarsan further study of its action is necessary before definite conclusions can be drawn. Silver salvarsan and mercurosal also gave excellent results when both were administered intravenously, and when intensive treatment with both was the rule. The mercury content of mercurosal is higher than the usual salts of mercury employed, but its toxicity is lower, so that if proper attention to the power of elimination possessed by the patient is given, and his tolerance carefully watched, higher doses of mercurosal may be given without danger, and severe mercurialism or stomatitis is less common than with other preparations. Spiegel adds that patients who have once received mercurosal intravenously invariably rebel against the use of the insoluble salts of mercury by intramuscular injection. He has not found any injury follow its use alone or in conjunction with silver salvarsan.

### 37. Treatment of Diarrhoea.

R. D. RUDOLF (*Canadian Med. Assoc. Journ.*, May, 1926, p. 501), classifies the various types of diarrhoea and outlines the corresponding treatment. Anatomically they may be classed as high, middle, and lower, depending upon whether the stomach and duodenum, the small and upper large intestine, or the colon and rectum, are the seat of the mischief. Etiologically he classifies them as nervous, purgative, and organic. In nervous diarrhoea due to disturbed innervation the use of the bromides is indicated, combined with belladonna if colic is present; minim doses of liquor arsenicalis before meals help that form in which the contents are hurried on so quickly that undigested food may appear in the stools. Purgative diarrhoea due to some substance swallowed or elaborated in the stomach or bowel is accompanied by colic, with relief until the next stool; achylia, absence of hydrochloric acid, chills, or bacterial decomposition may be the causative factor, the condition subsiding after the elimination of the irritant by natural or medicinal purging. Such cases, however, may pass into the third group of organic diarrhoea from the resulting catarrh. In this third type

some pathological change in the intestinal mucosa exists, causing increased secretion and peristalsis. Rest, warmth, and restriction of diet and purgatives are indicated, and bismuth, chalk, and opium mixtures are useful, and in acute watery diarrhoea kaolin given freely is valuable. In diarrhoea of the lower bowel a rectal examination should be made to eliminate an impacted faecal mass or growth, and tenesmus may be relieved by starch and opium enemas. In very chronic cases an appendicostomy, with irrigation of the whole colon from above, may be necessary. Rudolf regards mucous colitis as resulting from a general nervous condition and requiring general rather than local treatment, though benefit may be derived from bland normal saline or sodium bicarbonate douches or from treatment at Harrogate or Plombières.

### 33. Subcutaneous Injections of Nascent Oxygen in Whooping-cough.

G. BOELDIEU (*Paris Méd.*, April 24th, 1926, p. 401) refers to an article published in 1921 by Chatinéro on 40 cases of whooping-cough treated by oxygen, and reports three cases confirming the value of this treatment in children aged from 22 months to 5 years. Subcutaneous injections of nascent oxygen were given by a special apparatus, the doses ranging from 50 to 100 c.cm., and the number of injections from five to seven. After the fifth injection the children had peaceful nights and stopped vomiting, and after seven injections complete recovery took place without any other treatment. When given slowly the injections were painless and were well tolerated by the children.

## Radiology.

### 33. Non-Opaque Foreign Bodies in the Air Passages.

W. F. MANGES (*Brit. Journ. Radiol.*, April, 1926, p. 119) thinks that the x-ray diagnosis and localization of a non-opaque foreign body lodged in the bronchus may now be made with almost the same degree of certainty as is the case with an opaque foreign body. Repeated examinations will reveal all foreign bodies lodged in the trachea with the exception of a very small percentage; the few remaining cases can be diagnosed by physical signs, because the foreign bodies are of such a shape and size as to be freely movable in the trachea and they do not cause expiratory obstruction. With opaque foreign bodies the lung shadows are of comparatively little importance in diagnosis, but in detecting non-opaque foreign bodies the diagnosis may turn upon the interpretation of the shadows of every part of the lung field as well as of the mediastinal structures, the diaphragm, and the chest wall. In dealing with a non-opaque foreign body exposures must be made during inspiration and expiration, and so rapidly that the motion of respiration may not blur the film. Non-opaque foreign bodies are almost always vegetable, such as nut kernels, seeds, maize, beans, shells, and roots. As a rule they produce more inflammatory reaction than metallic and other inorganic substances, and they may give rise to obstructive emphysema, atelectasis, "drowned lung," or lung abscess, either alone or in combination. When the foreign body is in a bronchus x rays will show increased transparency of the affected lung, depression and limitation of motion of the diaphragm on the affected side, and displacement of the heart and mediastinal structures to the unaffected side at expiration. When the trachea is concerned the signs will be increased transparency of both lungs, depression and limitation of motion of both diaphragms, and rotation of the heart so that its transverse diameter is less at expiration than at inspiration. In atelectasis the obstruction is more complete and the radiographical appearance is the opposite of that seen in obstructive emphysema. In "drowned lung" the exudate appearing distally to the foreign body gradually fills the smaller bronchi and air vesicles and adds density to the lung shadow. Remarkable variations may be seen at different observations in an individual case and localization is based upon the area of the lung involved.

### 30. X-Ray Treatment of Laryngeal Papilloma.

I. SOLOMON and A. BLONDEAU (*Journ. de Radiol. et d'Électrol.*, March, 1926, p. 112) state that laryngeal papillomata, though comparatively rare, may become malignant after the age of 40; the prognosis in childhood is also serious. Being situated on the vocal cords, the ventricular bands, and subglottic region, they produce severe dyspnoea, and tracheotomy is usually required. Surgical treatment is usually followed by relapse. The prognosis has been much improved since the introduction of x-ray treatment. The authors describe the case of a youth, aged 17, who suffered from dyspnoea and

progressive aphonia. Tracheotomy was performed in 1920, and numerous operations for the prevention of asphyxia had been required before and since that date. When x-ray treatment was first employed the vocal cords were almost completely hidden by cauliflower-like papillomas. During a period of four weeks the patient received a total dosage of 7,000 Behnen's units, the treatment being applied alternately to each side of the neck. Deeply penetrating rays from a 40 cm. spark were used, filtered through 0.5 mm. copper and 2 mm. aluminium. A dose of 1,000 units was applied twice weekly. After the third treatment the tracheotomy tube was no longer required and the papillomas were much smaller, and one month later the voice was almost normal. Six months subsequently the patient remained quite cured. The larynx showed some scarring at the site of the papillomas and there was some deformity of the left vocal cord. The tracheal fistula had closed spontaneously. The authors refer to two previous patients, treated in 1920 and 1921, who remain entirely cured. They state that x-ray treatment is preferable to any other in this disease.

### 41. Whooping-cough Treated by X Rays.

A. PINÓS and J. M. PUJADAS (*Rev. med. de l'arcelona*, May, 1926, p. 447), who record eight cases in children aged from 4 months to 8 years, state that the good results reported by Leonard and Bowditch in the treatment of whooping-cough by x rays (*Epitome*, November 29th, 1924, para. 424, and December 20th, 1924, para. 491) induced them to employ this method in the Santa Cruz Hospital at Barcelona. They attribute the success obtained to the rapid transformation of lymphoid tissue into scar tissue, the paroxysms diminishing in intensity and disappearing within the first few days of treatment. The tracheo-bronchial glands, which undergo enlargement as the result of toxic inflammation, after vigorous irradiation show hyperplasia of their connective tissue, which on contraction causes diminution of its size and consequent disappearance of the principal source of irritation of the vagus and recurrent laryngeal nerve which is the cause of the infective catarrh.

## Obstetrics and Gynaecology.

### 42. Treatment of Persistent Occipito-posterior Presentations.

C. S. BACON (*Journ. Amer. Med. Assoc.*, February 13th, 1926, p. 465) estimates the frequency of the various relations of the foetal head to the pelvic inlet at the beginning of labour as follows: Left occipito-anterior presentation, 55 per cent.; right occipito-anterior, 15 per cent.; left occipito-posterior, 10 per cent.; right occipito-posterior, 20 per cent. Of the 30 per cent. primary posterior oblique positions, in about four-fifths of the cases anterior rotation occurs spontaneously, while in the remaining 6 per cent. about half the patients have large pelvis and strong uterine contractions, or the children are small and spontaneous delivery occurs without much difficulty. In the remaining 3 per cent. intervention is required, and Bacon has come to the following conclusions. After descent of the head complete dilatation of the cervix is generally necessary for the long or anterior rotation, and hence artificial rotation should not be attempted before the cervix is fully dilated. In persistent occipito-posterior presentation, as also in persistent deep transverse arrest of the head, manual rotation should be tried first, it being always remembered that it is of the first importance to change the extension of the head into flexion. If manual rotation fails, Bacon advises the application of Kielland forceps with their pelvic curve towards the occiput, and in the long occipito-mental diameter. The head should then be flexed and rotated, after which it may be delivered in the usual way. If manual rotation fails, and no Kielland forceps are available, he advises the use of Naegele or Simpson forceps in the Scanzoni manoeuvre, the forceps being applied to the occipito-mental diameter and the head being flexed before rotation is commenced.

### 43. The Kielland Forceps in Obstetrics.

L. AVERETT (*Therap. Gaz.*, March 15th, 1926, p. 153) describes the use of the Kielland forceps in obstetrics, defining their special advantages. The forceps can be applied biparietally in any position of the head, the part which can stand pressure best being selected; they fit close to the head, and can be used for rotation without danger of injury to the child or mother. The close fitting of the forceps on the head obviates slipping or change in the position of the head, without increasing the dimensions of the head, or hindering its normal mechanism; less force, therefore, is required for extraction. He cites various statistics in support of his claim that the use of Kielland's forceps diminishes foetal mortality and

maternal morbidity. Rosenfeld, in 1922, reported the results of 135 cases in which the forceps had been used. All the children were born alive, but four died subsequently; no child or mother showed any marked injury. Krull reports satisfactory results in ninety-three cases, in about half of which the pelvis was contracted. Hoffman, mentioning 116 cases, stated that delivery was rendered easy, particularly in flat pelvis where the head was high. Averett has recently used the Kielland forceps in twenty-two cases, with excellent results in all but one case, in which the woman had been in labour for twenty-four hours when he was called in. There being very great disproportion between the foetal head and the pelvis, he advised Caesarean section, but first tried Kielland forceps without success. The Caesarean section showed that no injury to the uterus or to the child's head had been caused, and both mother and child recovered well. He adds that before the application of these forceps the exact position of the head must be determined, as also the direction of the sagittal suture and the position of the large and small fontanelles.

#### 41. Rupture of the Uterus.

J. G. SHERRILL (*Surg., Gynecol. and Obstet.*, May, 1926, p. 657) discusses the possibility of rupture of the uterus following the administration of pituitary extract. A case is recorded in which there was a history of difficult instrumental delivery in a young healthy primipara with uterine inertia, and manual placental extraction followed by profuse haemorrhage and marked collapse. During labour she had received three 0.5 c.cm. doses of pituitrin at two-hourly intervals. No peritonitis developed even in the presence of infection and no organisms were recovered from the blood. She ran a septic temperature with rigors, and after expectant treatment a radical hysterectomy was performed on the thirtieth day, revealing two small tears on the peritoneal surface connected with a wide separation of the muscular and mucous coats. From this case and a study of others reported Sherrill concludes that the use of pituitrin early in labour may cause rupture, and he emphasizes the point that sudden collapse during or at the completion of labour with uncontrollable haemorrhage after delivery of the placenta may indicate the occurrence of uterine rupture, either partial or complete. Treatment consists in suturing the torn uterus if there is no doubt about the absence of infection; if there is doubt, hysterectomy should be performed.

## Pathology.

#### 45. Classification of the Bacilli of Malta Fever and Infectious Abortion.

M. BÉGUET (*C. R. Soc. de Biologie*, May 14th, 1926, p. 1187) has studied forty-two strains of *Brucella*, coming from cases of Malta fever, of *B. melitensis* infection in the goat, and of infectious abortion in cattle. Cultures of the same age on the same medium had the morphological aspect of cocci, coccobacilli, or bacilli; it was impossible to classify the strains by this method so that they should correspond with a classification by any other method. Many of the strains were agglutinated by non-specific serums, and many were flocculated by exposure to a temperature of 90°C. in saline suspension. There was a close agreement between the results of these two tests; the strains that flocculated on heating were the ones that agglutinated most strongly with non-specific serums. The agglutinogenic power of the strains varied considerably; as a rule the non-flocculable strains, on injection into rabbits, gave rise to a higher production of agglutinins than did the flocculable strains; but there were exceptions to this rule. Straight agglutination and absorption of agglutinin tests were tried; the results obtained showed that the agglutinability of each strain was different from that of every other strain. It was impossible, therefore, to group the organisms into any clear-cut divisions. From a consideration of the morphological, cultural, and serological reactions of the forty-two strains the author concludes that it is impossible as yet to lay down any definite classification of the organisms of the *Brucella* group.

#### 46. The Sedimentation Rate of the Erythrocytes.

O. BOUET (*Ugeskrift for Læger*, March 11th, 1926, p. 240) has investigated the rate of sedimentation of the erythrocytes in more than a hundred cases, using the technique described by Westergren. When the rate was normal, the test was repeated only two or three times in each case. In other cases it was repeated several times a day, notably in cases in which a close study was being made of the effects of protein shock treatment by injections of milk. In one group of cases of sciatica and muscular and articular rheumatism there were 35 patients, of whom 19 were treated with injections of milk.

The results were very good in 10 of these 19 cases, and in 6 others there was temporary subjective improvement. Ten of these 16 patients had been febrile before the treatment, and were rid of their fever in from four to seven days after its commencement. In nearly all these cases the protein shock treatment was followed by a rise in the sedimentation rate, which was unaffected only in 2 cases, and which became slower in a third case. The increase in the rate reached its maximum, as a rule, four or five days after the last injection. No definite conclusions could be drawn from the sedimentation test in these cases as to the choice of patients for protein shock treatment. The test was employed in 13 cases of definite or suspected tuberculosis, and proved of great value; it was found that when this reaction was persistently normal the presence of tuberculosis could be excluded. The reaction being in no sense specific, an abnormally rapid sedimentation rate could not be regarded as a definite sign of tuberculosis unless all the other causes of an increased rate could be eliminated.

#### 47. Human Intestinal Carriers of Tetanus Spores.

J. H. BAUER and K. F. MEYER (*Journ. Infect. Dis.*, April, 1926, p. 295) have made a survey of the distribution of tetanus spores in the faeces of persons in California. A small portion of faecal material was placed in beef-heart medium, heated to 70° to 75° C. for twenty minutes, cooled rapidly, and incubated for about a week. Smears were examined microscopically, and subcultures made from positive tubes into Tulloch's medium. After five days' incubation the growth was transferred to liver agar and pure colonies isolated; these were studied for toxicity and for serological type. Of 487 specimens from California 24.6 per cent. were found to contain tetanus spores. In addition to these 43 specimens from nineteen other States were examined, and in 9 tetanus spores were found. Data from other countries show a remarkable agreement with these figures; about one person in every four has been found to be an intestinal carrier of tetanus bacilli. The authors bring evidence to suggest that the bacillus lives chiefly in the caecum; that it is not a simple saprophyte living in the intestinal contents, but is rather a parasite of the intestinal wall; and that there is a mutual relationship between the tetanus bacillus and other spore-bearing anaerobes. They have never found the tetanus bacillus in the absence of these other organisms. The most common serological type was Type 1, which accounted for 63.3 per cent. of the Californian strains. The next commonest was Type 3, which accounted for 17.5 per cent. The remaining strains were divided between Types 2, 4, and 5. Type 6 was never found, but three strains were encountered which did not agglutinate with any of the six type serums. Whether these belonged to Type 7 was not determined.

#### 48. Varieties of the Tubercle Bacillus.

THÉRASSE (*Le Scalpel*, March 27th, 1926, p. 281) asserts that recent discoveries will shortly demand an entire revision of the accepted theories concerning the inheritance, infection, prophylaxis, and treatment of tuberculosis. Vaudremer's work on the non-acid-fast forms of the tubercle bacillus and on filterable forms has been confirmed by the researches of Bezançon and Philibert, and Thérasse believes that their results will give a new direction to the antituberculosis campaign. Vaudremer has shown that tubercle bacilli may be grown in a non-glycerinated potato medium, when they almost completely lose their acid-fast quality, but this is restored by subculture on glycerinated broth; moreover, the bacilli no longer produce tuberculin. After several subcultures in ordinary agar the bacilli are only slightly or not at all acid-fast, and may fail to infect guinea-pigs. Bezançon and Philibert conclude that the acid-fast type is a transition form only of the tubercle bacillus. It is possible that toxicity and virulence may be largely functions of acid resistance, which quality may depend on the condition of the lipid element. It has often been reported that in acute cases the bacilli may be short, sharply defined, and deeply stained, while in chronic cases they may be long, granular, irregularly stained, and ill defined. Thérasse is not convinced that the lipid envelope exists; it is more probable that the lipid element impregnates the whole body of the bacillus. Vaudremer has also stated that a growth of non-acid-fast branched elements develops rapidly in the filtrate through a Chamberland L3 filter of cultures of tubercle bacilli; these elements are stained by gentian violet. Injected subcutaneously into guinea-pigs they produce local induration, which disappears in about three weeks, but they do not cause generalized tuberculosis. These discoveries suggest that there is a special form of the tubercle bacillus, apparently connected with its reproduction—a stage in its life cycle. Bezançon and Philibert consider that the organism of tuberculosis is related to that of actinomycosis. Vaudremer's latest researches have led him to the conclusion that there are several types of tubercle bacilli.

K. MOSE: (*Jahrb. f. Kinderheilk.*, May, 1926, p. 273), who records two illustrative cases, states that degeneration of the brain may occur in the course of measles resembling the clinical picture of encephalitis. Only in rare cases does the degeneration prove fatal; as a rule either complete recovery takes place or more or less severe defects result. The condition is probably due to a toxic change, but whether the toxins are produced by measles or some other factor will only be known when the causal agent of measles is discovered. MOSE's cases were in a girl and boy, both aged 5½ years. The girl had at first an ordinary attack of measles with a temperature of 101° F. on appearance of the eruption. Five days later the temperature became normal, but in the evening of the same day she felt tired, and the temperature rose again next day, when she developed spasms of the extensor muscles of the arms and became unconscious. The cerebro-spinal fluid was clear, under high tension, and showed only a slight increase of albumin and no diminution of sugar. The reflexes were partly lost. Typical signs of basilar meningitis were absent, and the clinical picture was more suggestive of encephalitis. The boy developed measles in the second week of an attack of whooping-cough. The measles ran a normal course, and seven days after appearance of the eruption the temperature fell to normal, but the patient showed psychical symptoms with disturbance of the bladder and rectum in the course of the next few days. Symptoms of affection of the vegetative nervous system were also present in the form of sweating and dermatographism. After the temperature had been normal for four days it rose again, coma set in, and death occurred with a rise of temperature to 105.6° F. In both cases the brain was of tough consistence and preserved its shape after removal from the skull. The gyri were obliterated and there was considerable congestion. The weight of the girl's brain was 1,380 grams and of the boy's brain 1,400 grams, as compared with the weights of 1,220 grams in a normal girl and 1,230 grams in a normal boy. The meninges showed only moderate oedema in one case and only slight haemorrhages in the other. Histological examination showed similar changes in both brains of a purely degenerative character and an entire absence of inflammatory lesions in the form of infiltration of the vessel walls with lymph cells.

#### 

MAY R. MAYERS (*Journ. Indust. Hygiene*, May, 1926, p. 222) has investigated the blood changes in lead poisoning from the standpoint of diagnosis in 381 cases among lead workers who were all at work; no cases of incapacity or acute poisoning were included. In 62 per cent. lead anaemia was found to be a definite blood disease entity, the diagnostic features being that the red cell count and haemoglobin were only slightly reduced, except in severe cases, thus giving the appearance of a very mild secondary anaemia, and that the colour index averaged only a little less than 1, but became lower as the red cell count and the haemoglobin were reduced. She states that in lead anaemia changes in the morphology of the red cells are out of all proportion to those found in an ordinary case of secondary anaemia; stippling ranked fourth in frequency, being present in 39 per cent. of those cases in which blood changes were present. Though more prevalent in lead anaemia than in other secondary anaemias, stippling is only one among a number of pathological changes, and it should be considered together with the rest of the blood picture, stippling and polychromatophilia occurring in the same percentage of cases though one frequently occurs without the other. The white cell count was almost normal with a slight relative lymphocytosis at the expense of the polymorphonuclear leucocytes; the mononuclear cell count was slightly increased. The pallor of lead poisoning does not appear to have any definite relation to the red cell count, the haemoglobin content, or the severity of the intoxication, but seems to be due to some neuro-vascular capillary disturbance. Diagnosis of lead anaemia depends upon examination of the whole blood picture, and more than one slide should be examined, since many cells, especially if stippled, appear intermittently in the circulation. The recognition of lead anaemia as an entity increases the value of the blood examination, and in difficult compensation cases these findings, either with or without stippling, may establish an otherwise doubtful diagnosis.

#### 

M. HADVOGL (*Münch. med. Woch.*, February 26th, 1926, p. 358) has recently observed twelve cases of diphtheria in children with a negative Schick reaction. In five cases the antitoxin content of their serum was determined, and from 0.01 to 0.45 antitoxin unit was found in 1 c.cm. of serum. In most of the cases the disease was nasal diphtheria, in two the tonsils were affected, and in one instance the larynx and the tonsils. A possible explanation of these cases is that a diminution of the antitoxin in the blood was the cause of the attack, and that at the time of examination the disease was on the way to recovery owing to a fresh increase in antitoxin. In any case these observations indicate that, contrary to the generally accepted view, diphtheria patients may have antitoxin in their blood, as shown by the Schick reaction and direct examination of the blood. The practical conclusion drawn from them is that a negative Schick reaction does not contraindicate with certainty the presence of diphtheria.

#### 

F. HARBITZ (*Norsk Mag. f. Lægevid.*, May, 1923, p. 371), during the last twenty-five years, has examined twenty-two definite cases of Addison's disease, and constantly found considerable changes in both suprarenals, of which almost the whole substance was destroyed, remnants of normal structure being found in most cases in the cortex only. In twenty cases the lesions of caseous tuberculosis were present, in two there was a chronic inflammation with atrophy which was neither syphilitic nor tuberculous, and in one of the latter there were signs of a regenerative process. In addition to these twenty-two cases Harbitz has also examined numerous cases of destructive suprarenal processes affecting only one suprarenal or the second partially, but without the development of Addison's disease. In two cases in which the clinical diagnosis of Addison's disease was doubtful the suprarenals were found to be normal at the autopsy.

#### 

J. M. STURTEVANT (*Journ. Amer. Med. Assoc.*, May 8th, 1926, p. 1436), who records an illustrative case, states that meningococcus meningitis is an extremely rare disease in early infancy. Root, in 1921, found only six cases on record in infants under 2 months of age. Two of these died during the acute stage of the disease, three a few months later from sequels, and one could not be traced. Bell and Cook, in 1922, recorded a case in a child, aged 17 days, of fulminating parameningococcus infection and extensive petechial rash. Sturtevant now reports a case in a female infant, aged 7 weeks, which was remarkable for the mild character of the meningeal symptoms. Complete blocking of the spinal canal occurred, necessitating administration of seven injections of serum into the clisterna magna. Although an acute pneumococcus infection supervened within sixty days of the onset of the primary disease, complete and uncomplicated recovery ensued, and the child was in good health when seen nine months after the disease.

#### 

N. FIESSINGER (*Ann. de méd.*, April, 1926, p. 428) records his observations on fourteen cases of ascites in subjects of alcoholic cirrhosis aged from 35 to 47, of whom six were men and eight women. The duration of the intoxication is important, as the ascites is only curable when the intoxication is recent, in contrast with the long-standing intoxication associated with certain occupations, such as those of wine merchants, carters, and furniture removers. There was nothing peculiar in the character of the ascites in Fiessinger's cases. The fluid never produced tuberculosis in guinea-pigs, but the Wassermann test was positive in the serum of five cases and in the ascitic fluid of three. In three instances the Wassermann test as an indication of syphilis was confirmed by the history or other evidence of the disease. In some cases the ascites showed a rapid progress at first and then became stationary at the end of three or four weeks. Ascites which made little advance at first, but was gradually progressive, was most likely to recur. In six of the fourteen cases paracentesis was required—in one four times, in two twice, and in three once. If possible, paracentesis should be avoided, as it causes an irritation of the peritoneum which is shown by a change in the cytological formula, in which lymphocytosis rapidly predominates. Rest in bed and a milk and vegetarian diet poor in chlorides is an essential condition for producing a cure. In six cases the ascites was cured by

one or two series of twelve intravenous injections of mercury cyanide in doses of 1 cg. every two days; in two cases by one or two injections a week of quinine and bismuth; and, in the remaining six, laxatives and hepatic opotherapy were sufficient to produce a cure. The subsequent history of only six patients was discovered. Five resumed their alcoholic habits and had a recurrence of ascites after a period ranging from two to six weeks, and in only one case did the ascites not reappear in spite of the patient's return to drink. Flessinger excludes tuberculosis from the causation of ascites in his cases, and does not think that the ascites in alcoholic cirrhosis is always syphilitic, in spite of the favourable action of mercury and bismuth; but considers that the good result is due to the action of mercury and bismuth on the hepatic parenchyma, in which they provoke a revival of cellular activity.

##### 55. Diastolic Hypertension in Adult Congenital Syphilis.

C. LEGRAND (*Arch. Mal. du Cœur, des Vaisseaux et du Sang*, June, 1926, p. 384) confirms Gallavardin's observation that diastolic hypertension, accompanied by a normal systolic blood pressure, indicates serious loss of equilibrium in the circulation, and implies myocardial weakness and venous congestion. Diastolic hypertension occurs in serious subacute or chronic nephritis associated with cardiac dilatation, and to a lesser degree in cardiac hypertrophy and dilatation with venous congestion or severe emphysema. Legrand describes several cases. He thinks that hypertension in a young subject suggests acquired syphilis, but he has found diastolic hypertension in several men whose ages varied from 21 to 48 years, and who had positive Wassermann reactions with a definite history of congenital syphilis. He states also that a diastolic hypertension of 100 mm. Hg must always be regarded as a serious symptom requiring careful investigation.

##### 56. Recurrent Swelling of the Parotid Gland.

S. WOLFF (*Jahrb. f. Kinderheilk.*, May, 1926, p. 334) records the case of a male infant aged 2 months, the subject of oesophageal and pyloric spasm, who on several occasions developed swelling of the parotids lasting from two to three hours. No crepitation could be detected, so that emphysema could be excluded, and infection of the parotid could also be eliminated, as the swelling subsided in a few hours. Wolff was inclined to attribute the swelling to a spasm of Stensen's duct, as the result of which the evacuation of the abundant saliva was obstructed, giving rise to a strong hard swelling. This suggestion harmonizes with spasm present in other parts of the alimentary tract.

## Surgery.

##### 57. Torsion of the Spermatic Cord.

V. C. IRK (*Zentralbl. f. Chir.*, June 5th, 1926, p. 1437) reports two cases of torsion of the spermatic cord, of which only seventy-six cases have been described hitherto. In addition to the generally recognized causes of this accident, Bardy has suggested that in patent tunica vaginalis, the cord remaining free throughout its entire length is more easily twisted than when it is fixed in the inguinal canal. The general clinical symptoms resemble those of acute intestinal obstruction—peritoneal irritation, collapse, vomiting, abdominal pain, and reflex intestinal obstruction. There is swelling in the inguinal canal, or in the affected half of the scrotum, closely resembling strangulated hernia. If the testicle is palpable it may be possible to distinguish between the swollen epididymis and the mass of congested spermatic veins. Irk's first case was one of cryptorchism, associated with torsion; his second was a bilateral hernial hydrocele, associated with a hernia and a twisted spermatic cord; such an association of torsion of the cord with congenital hernia does not seem to have been recorded previously. The first patient was a healthy boy, aged 16, who, two days prior to admission, after lifting a heavy weight, was attacked by severe abdominal pain, collapse, and vomiting. Four hours later there was an increasing swelling in the right groin; no relief followed rest in bed. On the third day strangulated hernia was diagnosed; there was no great muscular rigidity, no vomiting, and no passage of faeces or flatus. In the right groin an oval and very tender tumour, as large as a man's fist, was found; it was quite irreducible and a varicocele-like mass of twisted veins was plainly felt. The testis was rotated clockwise through 90 degrees; as it was quite gangrenous it was removed. The patient made a rapid recovery. The second case was that of a healthy man aged 24, who, since childhood, had observed a constantly increasing swelling in the right side of the scrotum; this, though larger than his fist, was easily reducible. While sitting down on the evening

before admission to hospital the hernia descended and he was unable to reduce it. Typical signs of acute obstruction appeared, but his general condition was good. The right side of the scrotum was tensely swollen to the size of two fists, and was very tender. The swollen testis lay above the hydrocele and was rotated clockwise through 90 degrees. On opening the sac blood-stained serum escaped and a loop of small intestine, also twisted upon itself, was found. This was slightly swollen and congested, but was easily returned through the large hernial orifice. The testis was congested but not gangrenous; it was fixed in the normal position and the very long cord was shortened by making a U-loop; a drainage tube was inserted and a Winkelmann-Bassini operation for radical cure of the hernia was performed. In a month the greatly swollen testis was reduced to its normal size.

##### 58. Treatment of Old Congenital Dislocation of the Hip.

L. C. ABBOTT (*Arch. of Surg.*, May, 1926, p. 983) points out that in old congenital dislocations of the hip it is often difficult to secure reduction by the usual methods of treatment because of the marked pathological changes that have taken place in the joint. After the age of 10 the force used in the so-called "bloodless method" may cause serious injury to the vessels and nerves. This condition, if left till adult life, is productive of severe disability, and palliative measures often fail to give any relief. The cause of failure to produce reduction in these cases is chiefly a shortening of the soft parts of the hip and thigh which fixed the head of the femur well above the acetabulum. Further, the acetabulum is poorly developed and filled with fat and fold of capsule. The first indication in treatment, therefore, is to overcome this shortening so that the head of the femur can be brought down; the second is to clear the acetabulum. Skeletal traction is effective in stretching the contracture of the soft parts and bringing the head down, and this is best applied by the Steinman pin through the shaft of the femur. Reduction is finally obtained by open operation; either arthrodesis may be performed or an attempt made to preserve motion. In five recorded cases there was improvement in the length of the leg and in the gait. Where bony ankylosis was obtained the results were best for weight-bearing, and this procedure gave the most satisfactory functional result. The end-results where movement was preserved were not so satisfactory.

##### 59. Surgical Treatment of Splenomegaly.

A. TROELL (*Lyon Chir.*, March-April, 1926, p. 137) records fifteen cases where surgical measures were undertaken to deal with enlargement of the spleen. Eight patients had Banti's disease, three haemolytic jaundice, two pernicious anaemia, one repeated haemorrhages, and one tuberculous infection of the spleen. In thirteen cases splenectomy was performed, while in two some of the vessels at the hilus of the spleen were ligatured. There was no operative mortality. Troell states that the effect of splenectomy in carefully selected cases is generally very satisfactory; in Banti's disease a complete cure may be expected. Even when there is bile in the urine, and ascites, and changes in the liver, the result may be favourable. From the operative standpoint it is useful to classify the cases of Banti's disease into three stages, depending on the duration and characters of the symptoms. If the onset is fairly recent, but there is a severe degree of anaemia, the prognosis is less favourable than in the more chronic cases, where the abdominal condition is more in evidence than the blood changes. Even where the changes in the blood—leucocytosis, eosinophilia, and the presence of nucleated red cells—persist after the operation of splenectomy the outlook is not unfavourable. It sometimes happens that the patient's resistance to other infections may be altered for a time after operation. Where splenectomy is contraindicated it may be necessary to resort to ligation of some of the splenic vessels; this seems to lessen the activity of the spleen in these conditions with a satisfactory result.

##### 60. Anal Fistula and Tuberculosis.

A. FERRE Y FERRE (*Arch. de méd., cir. y esp.*, January 9th, p. 54, and January 16th, 1926, p. 104) remarks that it has been stated that the majority of fistulas are primarily tuberculous, although this is not a well established fact. At St. Mark's Hospital Lockhart-Mummery found tuberculosis in only 15 to 20 per cent. of his cases of fistula, and Gabriel at the same hospital, as the result of histological examination and inoculation of guinea-pigs, found tuberculosis present in only 15 per cent. Although it is certain that anal fistulas are very frequent in tuberculous subjects, this does not imply that most fistulas are tuberculous. According to the statistics of the Brompton Hospital, fistulas were found in only 4 per cent. of the tuberculous patients. Douglas Powell estimated the

frequency of fistulas in tuberculosis at 5 per cent., and Taylor at 1 per cent. Among 1,000 cases of fistula treated by Giant groups of anal fistula showed evidence of tuberculosis. Three groups of anal fistula may be recognized in association with tuberculous: (1) non-tuberculous fistula in subjects of pulmonary tuberculosis; (2) tuberculous fistula in persons who do not present any obvious pulmonary lesions; (3) tuberculous fistula in subjects of pulmonary tuberculosis. In the first group operation is rapidly followed by recovery; in the second the part of the surgeon; in the third group the post-operative outlook is very gloomy, and extensive tuberculous ulceration of the colon, rectum, and skin of the anus is frequently present. The author comes to the conclusion that the relation supposed to exist between anal fistula and tuberculosis is merely of historical interest, and that anal fistula may coexist with tuberculosis as it may with any other affection.

#### 64. Typhoid Abscess of Breast.

P. O. SNOKE and J. L. GORRUTH (Amer. Journ. Med. Sci., April, 1926, p. 555) report a case of the rare condition typhoid abscess of the breast. The patient was a young negroess, aged 18, who, after a normal pregnancy and labour, weaned the child because lactation was deficient. Small lumps subsequently appeared in her breast, but gave no trouble. On admission to hospital she had a temperature of 103°, pulse 113, and respirations 22; there was no evidence as to the onset of the pyrexia. The physical examination showed slight bronchitis; rose spots and splenic enlargement were not noted; there was a slight leucopenia. The Widal reaction was negative, but *D. typhosus* was found in blood cultures. The Wassermann reaction was negative, and three examinations of the stools for typhoid bacilli were unsuccessful. The course of the fever was mild, but about twelve days after her admission to hospital a firm lump, rather more than an inch in diameter, was discovered in the lower inner quadrant of the right breast. On each side of this lump were two smaller ones; they were not fixed to the skin or chest wall; there was no fluctuation, and the swellings were not hot or tender. The possibility of the presence of tuberculosis or new growth was considered, but surgical treatment was at first refused. Two months later the mass in the breast was half its original size, but was at one point fixed to the skin and fluctuation was elicited. The breast was amputated, and in dissecting back from which pure cultures of *D. typhosus* were obtained. The post-operative history was uneventful. The amputated breast showed a large thick-walled abscess, the cavity of which was the size of a golf ball, and the wall varied in thickness from 4 to 23 mm.; it was filled with an orange coloured putty-like material. Small discrete bodies resembling lymph nodes were embedded in the axillary mass of fat. The authors think it probable that the three post-lactation masses were periductal adenofibromata which had become foci for typhoid bacilli. The enlarged axillary masses were adenofibromata. The differential diagnosis between tuberculosis and neoplasm could not be made before the breast was removed.

### Therapeutics.

#### 62. Palliative Treatment of Inoperable Cancer.

J. K. NARAT (Med. Journ. and Record, April 21st, 1926, p. 491) considers that in cases of inoperable cancer the most strenuous efforts should be made to obtain comfort and relief from pain and other distressing symptoms. In addition to general hygienic rules, and the avoidance of carbohydrates in the diet, since these have been shown to stimulate the growth of malignant neoplasms, potassium in the diet should be replaced by calcium. The author recommends that cooked vegetables should form the bulk of the dietary, with abundance of fruit; while beans, uncooked tomatoes, fresh bread, and condiments should be forbidden. Cachexia may be combated by giving a large amount of distilled water, either plain or with fruit juices. Constipation should be treated by a liberal use of hot water, fruits, or paraffin, but the saline laxatives should be avoided owing to the amount of water they withdraw from the body. The pain may yield to bromide preparations if a neurotic element is present, and suppositories containing 5 grains of antipyrin and one-sixth of a grain of belladonna extract may be helpful. Opiates should be saved for the later stage of the disease, and luminal and its allies used first. In extremely severe pain a combination of morphine with magnesium sulphate gives the best results. In oral cancer mouth-washes containing boric acid or tannic acid will be found soothing. In cancer of the stomach gastric haemorrhages may be stopped by lavage with very hot water, containing a few drops of a 1 in 1,000 solution of adrenaline, together with the application of heavy

bandages over the epigastrium. For the local treatment of external cancers, Narat recommends the avoidance of any irritant or stimulant preparations, and advises the use of pastes containing arsenic and mercury, liquid caustics, such as chronic acid, and a 2 per cent. aqueous solution of formalin. Martenstein's salt paste, first recommended for the treatment of lupus vulgaris, is also useful. The unpleasant smell of ulcerating growths may be controlled by local applications of granulated sugar, but, in view of the possibility that nourishment may thus be provided for the cancer cells, this treatment should be confined to very advanced stages of the disease. Powdered animal charcoal is also very effective, as also is a dusting powder of potassium permanganate and resorcin.

#### 63. Therapeutic Value of Red Rays.

G. M. LEWICK (British Journ. Radiol., May, 1926, p. 185) has studied the therapeutic possibilities of the red rays in view of the beneficial results of sunlight on the muscles of persons suffering from tuberculous arthritis. Owing to the absorption of other rays by the water content of the tissues and the blood, red rays alone produce direct effects on the deeper tissues. The red rays were found to be absorbed by muscles and by inflammatory exudates. Cases of acute anterior poliomyelitis were investigated, in some of which the muscles showed complete degeneration reactions and no contraction could be obtained by the interrupted galvanic current. While the red rays were being administered special measures were also taken to preserve the nutrition and to prevent stretching of the paralysed muscles. Carbon filament vacuum lamps were used because they yielded light richer in red rays and infra-red frequencies than metal filament lamps in gas-filled globes. Red-stained soda glass screens were interposed in order that the maximum intensity of red rays might be used without overheating the skin; a reflector was used to direct the rays, the lamp was placed at a distance of two feet from the part affected, and daily exposures were given. In four children who had had anterior poliomyelitis, and in two patients with tuberculosis of the leg and knee, encouraging results were obtained, and chronic ulcers healed rapidly; the treatment is also recommended for lupus and acute inflammations. The author believes that irradiation with red rays produces in the deep tissues an increased power of resistance and repair and an improved nutrition.

#### 65. Argyrol in the Treatment of Aphthous Stomatitis.

M. PERRIS (Rev. Méd. de l'Est, February 1st, 1926, p. 94) states that aphthous stomatitis occurs very frequently among tuberculous patients. The ordinary alkaline treatment fails in the case of cachectic patients, among whom the disease frequently assumes a severe type. The author has discarded ordinary antiseptic applications and gargles or mouth-washes, in favour of a fairly strong solution of argyrol, applied freely to the lips, tongue, gums, and even to the tonsils. A sufficient quantity of argyrol (10 per cent.) solution should be applied, in order that it should not be too greatly diluted by the saliva. The author occasionally adds 30 to 50 per cent. glycerin to the water before mixing with the argyrol solution, particularly when the buccal mucosa is dry and thickened. The solution should be applied freely every two or three hours to the mucous membrane of the mouth, fauces, and pharynx. After the first applications the progress of the disease is arrested, and, except in patients who are moribund, it may disappear from the mouth in three or four days. In the nasopharynx and oesophagus the infection is more obstinate, but nevertheless it improves under treatment. The author insists on the importance of frequent inspection of the mouth and pharynx in cases of phthisis, as the disease spreads so rapidly. He adds that argyrol has a definitely prophylactic action and is far more potent than protargol, the latter containing only 8 per cent. while the former contains 30 per cent. of silver. Argyrol is freely soluble in cold water, which should always be employed. Cotton-wool tampons may be replaced by camel-hair brushes if the former cause pain. Argyrol solutions usually cause little or no pain, especially when used prophylactically or in early cases of stomatitis, when they relieve dysphagia, enabling the patients to take food more freely.

#### 65. Thyroidin in the Treatment of Obesity.

A. J. CORO (Rev. de med. y cir. de la Habana, March 10th, 1926, p. 151), who records an illustrative case, while maintaining that thyroidin is of great value in the treatment of obesity, urges that before administering the drug the patient should be carefully examined and an opinion formed as to the general condition in view of the fact that sensitiveness to thyroidin is of supreme importance though subject to extreme variations. In the first place it should be noted that in rare instances obesity may occur in association with hyperthyroidism, so that minimal doses of thyroidin are excessive. On

the other hand, obese subjects with symptoms of hypothyroidism are frequently met with. In such cases large doses are indicated which cause serious disturbance in normal persons. There is no doubt that cases of essential thyroid obesity occur which are almost always due to post-infective changes or tumours in the thyroid gland, goitre, and the like. But the most frequent examples of obesity are those cases of thyroid insufficiency which are due to the obesity itself. Super-alimentation gives rise to changes in all the glands, including the thyroid, testis, and ovary. Moreover, sensitiveness to thyroïdin appears to be associated with a special condition of the vagus and sympathetic. Persons who show definite evidence of sympathicotonus react violently to the drug, whereas vagotonic subjects can tolerate a fair-sized dose. The administration of suitable doses for the treatment of obesity—namely, 15 to 20 cg. of thyroid extract daily—is followed by cheerfulness, alacrity, muscular activity, slight acceleration of the pulse, rise of blood pressure, increase in the peripheral warmth and colour of the skin. This healthy state only disappears when administration of the drug is prolonged and the doses are very large, when it is replaced by a sense of fatigue in the lower limbs, neuralgia, headache, general asthenia, tachycardia, and irritability. Care always begins with a dose of 15 to 20 cg. and never gives it for more than ten days in succession. It is important that administration of the drug should be associated with the observance of a strict regimen.

#### 66. Coley's Fluid in Inoperable Malignant Tumours.

W. B. COLEY (*Therap. Gaz.*, March 15th, 1926, p. 157) gives a brief account of the origin, technique, and results of the treatment of inoperable malignant tumours by his mixture of toxins prepared from the *Streptococcus erysipellatis* and *B. prodigiosus*. He found that in many cases of inoperable malignant disease of all kinds, but especially sarcoma, the tumours disappeared during attacks of accidental erysipelas, and that no recurrence followed. He gives details of several cases treated by his method, and adds that, though he has never advocated the use of the mixed toxins in operable cases, yet in cases of sarcoma of the long bones, where an operation would involve the sacrifice of a limb, a preliminary brief trial of the fluid for three or four weeks is worth while, after which, if no marked improvement is noted, amputation is advised, followed by prolonged toxin treatment. In periosteal osteogenic sarcomas characterized by a considerable amount of new bone formation, no such preliminary treatment is advised. For an adult the initial dose of his mixed cultures is 0.03 c.cm., and for children correspondingly smaller amounts are used. The dose is increased daily by 0.03 c.cm., and if no marked rise in temperature has occurred after three or four injections the degree of increase is doubled. After the appearance of a pyrexial reaction three injections a week are sufficient. The treatment is continued with occasional intervals until the tumour has entirely disappeared, and thereafter for several months. Coley finds that the individual susceptibility varies and has to be taken into consideration. He originally tried intravenous injections, but quickly abandoned them; more recently he has returned to this method, but is still not prepared to recommend it as safe. He considers that the intramuscular injection is practically free from danger if the foregoing principles are observed; in more than 1,000 cases he has had only three deaths, due to embolism in two cases, when the general condition of the patients was extremely bad. He gives a statistical account of the results obtained by this method in lymphosarcoma, Hodgkin's disease, and sarcomas of the testis and long bones.

#### 67. Auto-transfusion.

V. C. M. LEESBERG (*Nederl. Tijdschr. v. Geneesk.*, April 17th, 1926, p. 1617), who records four successful cases, states that transfusion of the patient's own blood is not a new invention, as it was employed by Scribonius in 45 A.D. Auto-transfusion can be performed in two ways. The first method consists in intramuscular injection of the blood so as to cause a general reaction and possibly an increased formation of immunizing bodies. The second method, which is indicated in the treatment of boils, consists in injection of the blood between the infected and non-infected tissue, the object being not to cause a general reaction but to produce compression of the blood vessels and lymphatics by an increased tension of the tissues. Boils in the region of the nose and upper lip are particularly suited for this treatment. Incision of the boils is inadvisable, as this causes a diminution of the tissue tension, and enables the abnormal products of disintegration and the micro-organisms to become generalized through the blood vessels and lymphatics and causes death from septicæmia. But if the case is treated according to Læwen's technique the morbid focus can be dealt with without the risk of dissemination, as the injected blood shuts off the focus from the rest of the body for about a week, which is

a sufficient period to bring the infective process to a standstill. It is also supposed that the blood has a bactericidal action. According to Vorschütz the first method has both a specific and a non-specific action. On penetration of the bacteria and toxins the organism reacts by formation of antibodies. The patient's blood is thus an ideal specific serum. The non-specific action is an example of protein therapy. In the first method 50 c.cm. of blood is used, and in the second 25 c.cm.

## Disease in Childhood.

### 68. Spastic Paralysis in Infants.

JULES COMBY (*Rev. Méd. de la Suisse Romande*, March 10th, 1926, p. 130) groups these cases in three categories: (1) Little's disease, characterized by a spastic paraplegia; the condition is congenital, being due to intrauterine encephalitis, often of syphilitic origin. (2) Various spastic paralyzes—monoplegias, hemiplegias, paraplegias, etc.; they follow on epidemic encephalitis or some acute infection, and are due to a descending sclerosis of the pyramidal tracts. (3) Spastic obstetrical paralyzes due to accidental injury, instrumental or otherwise, at time of birth. All these forms commence with an inflammatory process of the cerebral motor area, which goes on to a descending degeneration of the pyramidal tracts. The prognosis depends on the degree and extent of the lesions. When there is much cerebral damage and signs of mental defect follow on the motor paralyzes the prognosis is almost hopeless. When the amount of paralysis is slight and intelligence is maintained considerable improvement can be expected, if not complete cure. Treatment in syphilitic cases should be specific. In all cases the author employs hot baths, followed by dry friction, passive movements, massage, and, later, education in active movements. He has had encouraging results from such treatment, which may, however, have to be continued for ten to fifteen years.

### 69. The Nervous Manifestations of Acetonaemia in Children.

F. FORNARA (*Rev. di Clin. Ped.*, May, 1926, p. 296) reviews the literature and records five personal cases of acetonaemia in children aged from 2 to 7 years, characterized by nervous symptoms such as somnolence alone or somnolence alternating with restlessness and convulsions. Examination of the urine in all the cases during the occurrence of these nervous symptoms showed the presence of acetone or diacetic acid in considerable quantities. Examination of the cerebro-spinal fluid was made in only two cases, in both of which it was negative. Treatment by alkalis administered both by mouth and rectum caused a rapid disappearance of the symptoms, thus confirming the existence of a direct relation between the nervous symptoms and the acidosis. Fornara emphasizes the importance of distinguishing the nervous symptoms associated with acetonaemia from tuberculous meningitis and the various forms of encephalitis.

### 70. Acute Appendicitis in Children.

F. CHRISTOPHER (*Amer. Journ. Dis. Child.*, April, 1926, p. 525), from a study of the literature, concludes that the most important points in the diagnosis of acute appendicitis in children under 5 years of age are tenderness and rigidity in the right lower quadrant, leucocytosis, and abdominal pain. It is more common to mistake appendicitis for other diseases than vice versa. Acute appendicitis in these children is characterized by its insidious onset and rapid progress to perforation and gangrene. The mortality is high. The treatment is early operation, and the younger the child the greater the urgency of the operation. The gridiron incision of McBurney is the best. The appendix should always be removed, except in cases of large localized abscesses; when its removal would entail extensive soiling of the peritoneum. In such cases the abscesses should be adequately drained, and, if necessary, the appendix may be removed at a later operation. When operating in the presence of a spreading peritonitis the appendix should be removed with the least possible disturbance of the abdominal viscera. In the post-operative treatment the body temperature should be maintained and the patient kept as quiet as possible; the Fowler position is generally best. Food and nourishment must be given promptly. Repeated hypodermoclysis of a 3 per cent. glucose solution is recommended. Lavage with weak soda solution is useful in vomiting and gastric dilatation. Distension is treated by stupes, the electric pad, and administration of pituitary extract. Enemas are withheld entirely in the bad cases, or are given only with the greatest caution and with low pressure. In desperate cases of ileus the sewing of a catheter into the small bowel for intestinal drainage is advised.

71. **Diagnosis of Congenital Syphilis in Infants.**

L. NÜRNBERGER (*Zentralbl. f. Gynäk.*, March 20th, 1926, p. 785) describes the methods used in the diagnosis of maternal and infantile syphilis at the Universitäts-Frauenklinik at Hamburg, together with some results of treatment. Serological examination is made of retroplacental blood and of blood taken from the umbilical cord at birth. If either gives a positive Wassermann reaction the maternal blood is again examined before the patient's discharge from the clinic about the tenth day; non-specific reactions, which are not uncommon in non-syphilitic subjects at term, are thus detected. A second examination of the child's blood at this time is held to be unnecessary; a second negative test does not negative syphilis, for frequently a positive serological finding is not shown until the later appearance of clinical symptoms. Similarly a second positive Wassermann reaction is not necessarily a proof of syphilis and may be replaced in the course of a few weeks by a negative reaction. Great reliance, on the other hand, is placed on x-ray examination of the infant's extremities, which is made in the ninth week in every case in which there is a suspicion, on serological or clinical grounds, of congenital syphilis. Radiographic detection of bony syphilis is considered conclusive, and renders further blood examinations unnecessary. If x-ray signs are absent, however, the mother's and child's blood are again tested, and a positive result is taken to justify anti-syphilitic medication. The radiographic signs of congenital syphilis are those of (1) osteochondritis, with irregular increase of the calcification in the epiphyseal cartilage—most common in the femur, tibia and fibula, radius and ulna, or humerus, in the order named; or (2) ossifying periostitis of the long bones. In about one-fifth of the author's cases it has been possible to trace for periods of from two to five years infants suspected of syphilis at discharge from the lying-in home. Of these more than one-half showed signs of syphilis, either clinically, or indicated by late development of a positive blood reaction, or by radiographic examination of the long bones. With regard to the effective treatment, Nürnberger, collating his own cases with those reported in the literature, finds that 85 per cent. of syphilitic mothers treated during pregnancy give birth to healthy children, as compared with 41 per cent. of untreated.

## Obstetrics and Gynaecology.

72. **Diagnostic Value of Pituitary Extract in Obstetrics.**

W. ZORN (*Zentralbl. f. Gynäk.*, May 15th, 1926, p. 1315) mentions a number of conditions in which aid in diagnosis has been derived from the contraction of the pregnant uterus which follows the intravenous injection of pituitary extract. In the latter half of normal pregnancy this contraction is palpable within one minute, lasts from one to five minutes or even longer, and is followed by other shorter contractions; in the first half of pregnancy the uterine contraction following the injection within one minute may be somewhat shorter. The doses used were 0.25 and 1 c.cm. in the second and first halves of pregnancy respectively; the German preparation employed, which was found to be without danger for foetus and mother, is thought to be less concentrated than English preparations. In cases of rupture of the body of the uterus with escape of a large portion of the foetus into the abdominal cavity no uterine contraction after intravenous injection of pituitary extract is felt on palpation in the region of the fundus. In cases of suspected placenta praevia injections of pituitary extract may be of diagnostic assistance. The ensuing contraction of the uterus may lead to extrusion through the cervix of portions of placenta which previously had been impalpable, and one patient who had been admitted to hospital for placenta praevia and did not have further vaginal bleeding after repeated pituitary extract injections was later found to have a small bleeding mucous polypus. The contraction of the uterus in response to intravenous injections of pituitary extract was found to be of considerable help in the diagnosis of early pregnancy, including cases as early as the sixth week. In distinguishing between early uterine pregnancy and softened myoma the absence of a change in consistency of the uterus after the intravenous injection of pituitary extract is definitely against pregnancy, although its presence is not conclusively in favour of that condition. Therapeutically Zorn recommends intravenous injection of pituitary extract, not only in the third and sometimes the second stage of labour and in Caesarean sections, but also in cases of complete rupture of the uterus. Given as a preliminary to the digital or instrumental clearing out of the uterus in cases of abortion, it acts by diminishing the capacity of the organ and increasing the resistance of its walls.

73. **The Glycosuria of Pregnancy.**

M. LABBÉ and M. CHEVRI (Paris Méd., May 1st, 1926, p. 416) remark that the occurrence of glycosuria and lactosuria during pregnancy has been recognized since 1856, when Blot first found glycosuria in all his patients during delivery and lactation, and in about 50 per cent. of pregnant women. Later statistics have ranged between 4 and 100 per cent., but probably in many cases the method of examination was unreliable. The authors find that lactosuria may appear alone or in conjunction with glucose at any stage of pregnancy, but more frequently during the last three months; of 53 pregnant women, fasting glycosuria was present in only three cases. They conclude, therefore, that spontaneous glycosuria is far less common during pregnancy than was thought previously. They agree that a renal hyperpermeability to glucose is often present during pregnancy, although this condition is not constant enough to be reckoned as one of the signs of pregnancy. Renal hyperpermeability alone does not, however, offer an adequate explanation of the presence of glycosuria; other organs, and the sympathetic nervous system in particular, have been held responsible. The authors' personal observations have convinced them that severe glycosuria during pregnancy is connected with, and forms part of, the syndrome of hepatic insufficiency associated with destructive changes in the liver cells, urobilinuria, presence of amino-acids, and of acidosis. It is probable that other organs, especially the pancreas, are affected by the hepatic derangement. The glycosuric disturbance is usually transitory, but it recurs with increasing severity in each subsequent pregnancy, and it is probable that ultimately, in some cases, it terminates in true diabetes.

74. **Rupture of the Uterus.**

NOLANS (*Bruxelles Médical*, June 6th, 1926, p. 955) records a case of rupture of the gravid uterus successfully treated without operation. The patient, a primipara aged 37, with rachitic flat pelvis, had been given an injection of pituitary extract on the third day of a prolonged labour. After delivery by forceps of a living child, no part of which had entered the abdominal cavity, a longitudinal tear three inches long was found during manual removal of the adherent placenta in the anterior wall of the body of the uterus. Hysterectomy was considered too risky in view of the exhausted condition of the patient, who had a considerable degree of albuminuria as well as exophthalmic goitre and an acute superimposed on a chronic bronchitis. She was placed in Fowler's position with ice on the hypogastrium, and treated expectantly. Sixteen days later she was discharged from hospital in good condition.

75. GUENTHNER and SUZOR (*La Gynécologie*, March, 1926, p. 164) describe a case of spontaneous rupture of the uterus which occurred nineteen hours after commencement of labour in a 2-para aged 22; a tear in the left part of the lower uterine segment was discovered during manual exploration (on account of bleeding) after forceps delivery of a dead foetus presenting by the face and weighing 7 lb. 11 oz. At laparotomy a large subserous haematoma over the tear prevented recognition of the left uterine artery; hysterectomy was nevertheless performed, the uterine remnant being sutured with catgut and a Mikulicz drain inserted. The patient recovered after a febrile puerperium.

76. **Internal Haemorrhage from Haematosalpinx.**

F. PATTI (*Rev. d'Obst. e Ginecol. Prat.*, May, 1926, p. 246) records a case of extensive intraperitoneal haemorrhage from haematosalpinx, simulating an ectopic pregnancy. The patient, a 6-para aged 32, had contracted gonorrhoea two years previously during her last pregnancy and, after a febrile puerperium, had suffered from pelvic pain with painful and copious menses. A period of forty days' freedom from bleeding succeeded a menstrual interval of twenty days and was followed by severe pain and syncopal attacks. At the operation for acute anaemia ascribed to rupture of an ectopic pregnancy, the intraperitoneal effusion of blood was found to have come from a pervious distended Fallopian tube which contained a large blood clot; the smaller tube of the other side contained fluid blood. Microscopically no signs of ectopic gestation were detected, but well marked signs of subacute inflammation were present in the tubes of both sides; endometritis and sclero-cystic ovarian disease were also present.

77. **Relative Pelvic Contraction.**

J. TORRE BLANCO (*Arch. de med., cir. y esp.*, May 22nd, 1926, p. 337) regards a relatively contracted pelvis as one of which the true conjugate diameter is over 7 cm. with a full-term foetus of normal size. During gestation in cases of relative pelvic contraction expectant treatment only is required, and the patient should be removed to hospital during the last days of pregnancy. Blanco maintains that therapeutic

abortion is a scientific heresy, and that artificial premature labour has more drawbacks than advantages; it should be permitted only in exceptional circumstances. It is also only in exceptional conditions that the classical Caesarean operation should be performed in the later days of pregnancy; otherwise it should be delayed until the onset of labour. When labour begins, if the head is still movable, one should wait if possible until the lower uterine segment is fully formed. If the head becomes incarcerated and does not advance operation should be performed before there is any considerable compression of the soft parts, pelvotomy or Costa's symphysiotomy being most indicated in these cases. If the foetal head sinks into the cavity of the pelvis spontaneous delivery should be awaited or forceps applied if they are indicated. Basiotripsy should be confined to cases when the foetus is dead, and should only be allowed with a living foetus in some exceptional cases in private practice.

## Pathology.

### 78. The Antirachitic Effect of Irradiated Cholesterol after Crystallization.

I. I. NITZESCU and G. POPOVICIU (*C. R. Soc. de Biologie*, May 28th, 1926, p. 1301) have investigated the action of crystallization on cholesterol that has been irradiated by ultra-violet light. Merck and Kahlbaum's cholesterol was purified by three or four successive crystallizations, and was then submitted for one to two hours to the rays of a quartz lamp. Part of the irradiated cholesterol was kept as a control, and part was subjected to repeated recrystallization in 96 per cent. alcohol. After each crystallization the fraction remaining in the supernatant fluid was recovered by desiccation. Using rats that had been fed for four to twelve days on Sherman and Pappenheimer's rachitic dietary No. 84, they tested the effect of the irradiated and the non-irradiated cholesterol, and of the crystalline and the soluble fractions of the irradiated cholesterol. The results showed that the irradiated cholesterol lost its antirachitic properties after four recrystallizations and more completely still after six. The soluble fraction, however, remaining in the supernatant fluid was highly antirachitic, curing rats when administered in the proportion of 0.1 to 0.15 per cent. of the total dietary. A further series of experiments was made with digitonin. It was found that the fraction of irradiated cholesterol that was precipitated by digitonin was devoid of antirachitic power when added in the proportion of 0.1 per cent. to the dietary, whereas the non-precipitable fraction arrested the appearance of rickets even in the proportion of 0.002 per cent. The antirachitic power of irradiated cholesterol, therefore, appears to reside in the alcohol-soluble and digitonin-soluble fractions.

### 79. The Defensive Mechanism of the Parametrium.

T. HOFBAUER (*Bull. Johns Hopkins Hosp.*, April, 1926, p. 255), as the result of examining forty-three specimens of parametrium obtained from full-term pregnant uteri, reports that during pregnancy monocytes and clasmatoocytes appear in the base of the broad ligament and form a protective tissue with phagocytic powers, and that this mechanism is increased in prolonged labours, but more especially in cases where infection is present. The protective barrier is developed from "resting wandering cells" and from adventitial cells. This phagocytic tissue has to be seriously considered as affording a barrier to infection, its method of acting being biological, by phagocytosis; it thus provides a measure of local immunity in a site frequently exposed to invasion from infective agents and will absorb the debris of attacking micro-organisms. The exact mode of its production is not quite clear. The development of lymphoid tissue in the walls of the lymphatics supplying the parametrium may possibly be looked upon as an addition to the defensive forces opposed to infection.

### 80. The Heat-stable Peroxidase of Bacteria.

ANNE B. CALLOW (*Biochem. Journ.*, 1926, xx, No. 2, p. 247) has endeavoured to ascertain the nature of bacterial peroxidase. The term "peroxidase" was originally applied to an enzyme of the higher plants that was capable of imparting a blue colour to guaiacum in the presence of hydrogen peroxide. This enzyme was destroyed by boiling. Later it was found that certain iron-containing substances, such as haemoglobin, also gave the peroxidase reaction; since this enzyme, however, resisted boiling, it was called pseudo-peroxidase. The author finds that bacterial peroxidase resembles this latter enzyme in being thermostable. Suspensions of bacteria which had been washed several times were placed on a white dish; 2 drops of a freshly prepared solution of benzidine or of guaiacum and 2 drops of 20-volume hydrogen

peroxide were added. The presence of peroxidase was indicated by the appearance of a blue colour. The reaction occurred even after the organisms had been boiled for five minutes. It was noticed that the reaction after boiling was generally stronger than that given by the fresh bacteria and was permanent, whereas that given by the fresh bacteria faded away in about half an hour. This suggested that there might be a thermolabile reducing system in bacteria which was responsible for the fading. To test this the author examined the capacity of different organisms to reduce methylene blue, and found that as a rule those organisms which contained a methylene blue reductase all gave a fading blue colour with the peroxidase reagents. Moreover, sodium formate, which accelerates the reduction of methylene blue, increased the rapidity of the fading reaction, whereas propyl alcohol and cyclohexanol, which retard the reduction of methylene blue, decreased the rapidity of the fading reaction. The one anaerobe tested, *B. sporogenes*, gave only a slight peroxidase reaction.

### 81. The Number of Lymphoid Follicles of the Human Large Intestine.

C. DUKES and H. J. R. BUSSEY (*Journ. Path. and Bact.*, January, 1926, p. 111) have made a study of the lymphoid follicles of the large intestine and have worked out a technique which has enabled them to ascertain their numbers. The follicles are situated chiefly in the submucous coat, but a few are found between the two layers of the muscularis mucosae. From the submucosa the cells pass through the muscularis mucosae and appear to be discharged eventually into the lumen of the bowel. To calculate their frequency the intestine was fixed in 10 per cent. formal, washed in water, and the longitudinal muscle bands and the mucosa removed; the remaining portion was stained in 1 to 2 per cent. methylene blue and differentiated in dilute acetic acid. By this means the follicles showed up as bright blue spots, 1 to 2 mm. in diameter, against a faintly blue background. They were then counted by naked eye between two glass plates, the upper of which was etched in square centimetres. At least four pieces of intestine from different parts of the colon were examined. The results show that the average number of follicles per square centimetre increases from above downwards; in the ascending colon the mean was 3.24, in the sigmoid 4.18. Since the coefficient of variation is high the actual numbers in any given specimen may range from less than one to about seven. Altogether the intestines of 117 persons dying from various causes were examined. Children were found to have more follicles than adults, and patients dying from peritonitis had a higher average than normal. With this exception no association with any disease was noticed.

### 82. Histology of Aural Polypus.

P. RUSSI (*Arch. Ital. di Otol., Rinol. e Laringol.*, March, 1926, p. 126) has investigated the structure of polypi occurring in the ear, and has come to the conclusion that the great majority are inflammatory in origin; they present all the characteristics of innocence, but there is always some doubt where a blastoma has taken on the appearance of a polypus. The polypi of the tympanum may be divided into the following classes: (1) the hyperplastic type, including the mucoid polypus of Stendner and Duplay, the plasmoma, and the polypus associated with cholesteatoma; (2) the neoplastic type, which may include epithelial or connective tissue, or may be an endothelioma; and (3) the granulomatous type, which may be syphilitic or tuberculous. The diversity of the structure of the granulomatous type may depend on the outside factors affecting the infection and on the conditions under which the organism grows. The plasmoma is very vascular and is found to have plasma cells grouped around the vessels. In some cases a cholesteatoma may be found in the centre of a mass of polypoid tissue. The hyperplastic and neoplastic types behave according to the general laws of their particular type of tissue and may at the same time very closely simulate the inflammatory type.

### 83. Intestinal Absorption of Fat after Gastric Resection.

A. CIMINATA (*Arch. Ital. di Chir.*, February, 1926, p. 117) refers to his previous paper on the effects of gastric resection on the function and structure of the pancreas and alimentary absorption (*Epitome*, May 1st, 1926, para. 470), and records his further observations on dogs ten months after the Billroth II gastric resection, which prove that the capacity for absorption of fats, which is slightly diminished after the operation, subsequently returns to the normal. The conclusion is therefore justified that deviation of the acid duodenal chyme, as generally happens in exclusion of the pylorus in gastro-jejunostomy, does not involve a permanent diminution in the absorption of fats.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### Renal Rickets.

44. According to G. V. ASHEROFF (*Journ. of Bone and Joint Surgery*, April, 1926, p. 279), the clinical picture of renal rickets shows stunting with rachitic deformities, usually of late onset, and occurring with or without demonstrable kidney lesion. In renal rickets the urine is pale, of low specific gravity, and usually contains albumin. The deformity appears about puberty, and in the twenty-four cases collected there was a great preponderance among females. There was marked muscular asthenia, but no muscle wasting. The patients adopt an atonic posture when standing; the gait is waddling and they are scarcely able to lift the feet from the floor. Radiograms showed a general rarefaction and changes at the epiphyseal lines characteristic of rickets; split fractures were frequently seen. The change in the metaphyses predominates, with a hazy nephritis, while the kidneys showed chronic interstitial with increase of the suprarenals had thickened capsules, and the thyroid gland appears inactive in these cases. It is suggested that the connective tissue between the cells, and the thyroid gland appears inactive in these cases. Operation in condition arises from an ascending infection of the urinary tract which has spread to the suprarenals. The best treatment is cod-liver oil, calcium salts, and perhaps thyroid extract. Mas-ago and exercises should be given, and this may arrest the disease. Asheroff thinks that the evidence warrants the suggestion that the disease is due to fibrosis of the suprarenal gland.

45. Gerlier's Syndrome in Epidemic Encephalitis. H. VERGER (*Gaz. hebdom. des Sci. Méd. de Bordeaux*, March 14th, 1925, p. 164) records three cases of epidemic encephalitis in patients aged 17, 61, and 31 respectively, who presented the syndrome described by Gerlier in 1887 under the name of "paralytic vertigo," and later called "kubisagari" by the Japanese. The syndrome is characterized by attacks of asthenic paralysis chiefly affecting the extrinsic muscles of the eyes, the bulbar muscles, the muscles of the front and back of the neck, and in some instances of the arms. The vertigo is only a secondary phenomenon, and is the ordinary consequence of the visual disturbance or of staggering caused by paresis of the lower limbs. Neuralgias in various situations have also been described. Verger comes to the conclusion, first, that epidemic encephalitis may appear in a form resembling Gerlier's syndrome, and secondly, that the epidemic disease of Gerlier and the kubisagari of the Japanese were probably only episodes in epidemic encephalitis of which the existence was unknown prior to the work of Cruchet, Moutier, and Calmette.

46. Technique in Artificial Pneumothorax. W. NEUMANN (*Med. Klin.*, March 26th, 1926, p. 491) points out that while the success of artificial pneumothorax depends largely on the dexterity of the operator, the simplification of the apparatus used is, nevertheless, an important factor. He describes the outfit which he uses. This consists of two bottles, graduated and connected at their bases, and contained in a portable wooden box. The pressure is changed in these, not by raising or lowering the bottles, but by pumping in air by means of a pneumatic bulb. The bottles need not be moved, therefore, except in special cases when a very high pressure is required. Another feature is that the two taps connecting the bottles with the handle of the needle itself, and thus obviating the need for an assistant. The author employs ordinary air and considers it to be perfectly safe. He uses blunt needles for induction and sharp ones for refills, and thinks that in most cases the axilla is the most suitable point of entry.

### Prophylaxis of Measles.

47. R. KOCHMANN (*Deut. med. Woch.*, April 2nd, 1926, p. 565) states that in November, 1925, a prophylactic measles serum, obtained from animals and prepared under Degkwitz's direction, was placed on the market. Kochmann has recently employed this serum in a dose of 10 c.c.m. in nineteen children, aged from 9 to 21 months, who had been exposed to measles. All at the time of inoculation were healthy and afebrile, and some had been given quartz lamp treatment for rickets. Thirteen children, six of whom had

more or less severe serum sickness, contracted measles and only six escaped. The latter, however, afforded no proof of the value of the serum, since one had already had measles, one was of an insusceptible age (4 months), the third could not be followed up, the fourth died of nephritis in the incubation period, and in the remaining two the history of measles was uncertain. Two of the unsuccessfully inoculated children died of measles, and of the remainder five had normal attacks, and six had bronchopneumonia, otitis, or both, as complications. The serum sickness which occurred in more than a third of the cases was almost as severe as an attack of measles untreated by serum. Kochmann concludes that the new method should not take the place of convalescents' serum in the prophylaxis of measles.

### Hereditary Diabetes Insipidus.

48. G. MARAÑON and E. BONILLA (*La med. Ibera*, March 20th, 1926, p. 337), who record an illustrative case, remark that diabetes insipidus chiefly occurs in early life. Of fifty cases seen by Marañon about 75 per cent. developed the disease before 10 years of age. The onset of polyuria generally occurs in the years immediately preceding puberty. The disease is uncommon in the first two years of life: the earliest case is that recorded by De Luca (1915), whose patient was aged 3 months. Delafeld and Rachel have reported a case at 6 months, Variot one at 17 months, and Pincherle and Magni two cases at 12 months and 17 months. The present authors' case occurred in a male infant aged 1 year, whose parents noticed that he was passing urine frequently and in large quantities, and was constantly asking for water. When seen by the authors at the age of 20 months he was passing 8 litres of urine in the twenty-four hours and drinking approximately the same amount of water. The specific gravity of the urine was 1004. Injection of 1/2 c.c.m. of pituitrin caused the polyuria to fall temporarily to 4 1/2 litres in the twenty-four hours. There were no nervous symptoms or any evidence of pituitary lesions. X-ray examination showed a completely normal sella turcica. In view of the fact that all writers have emphasized the importance of the hereditary factor in diabetes insipidus, it is noteworthy that the child's mother suffered from polyuria.

### The Pigmentary Syphilide.

49. J. BEJARANO and J. A. GAY (*Arch. de med., cir. y esp.*, March 13th, 1926, p. 481), as the result of their personal experience and a study of the literature, come to the following conclusions: (1) Various causes distinct from syphilis may produce a clinical picture resembling properly pigmentary syphilide. (2) The pigmentary syphilide, as so called always follows a macular or papular syphilide type and is shown by the fact that vascular lesions of the suprarenal are always present. (3) The influence of the hypothesis of capsules may be regarded as certain. The origin of the Brandweiner and Alquist, who regard the origin of the pigmentary syphilide as a purely local one, is very doubtful. (4) The term "achromia" is not suitable, as the authors have never found a single point of the lesion in which pigment was completely absent. The term "syphilitic leucoderma" is therefore inapplicable. (5) A pigmentary syphilide in regions other than the neck does not appear to be influenced by the action of light.

### Alcoholic Amblyopia.

50. L. BUSSY (*Journ. de méd. de Lyon*, March 20th, 1926, p. 161) states that there has recently been an increased incidence of ocular disease referable to alcoholism, and particularly of retrobulbar neuritis. This condition, which was formerly chiefly seen in the out-patient department, is now equally common or even more frequent in private practice. It is difficult to say whether this is due to the spread of alcoholism to the upper classes or to a redistribution of the ocular lesions in the result of the war. The production of the optic nerve, said to be due to alcohol alone. Tobacco does not appear to play any part, so that the term "nicotine and alcoholic amblyopia" should be abandoned. Bussy has never seen a pure case of nicotine fibres or connective tissue of the optic nerve, affect the disease is primarily retinal, either by destroying but to act on the ganglion cells of the retina, either by rendering them directly, or rather by rendering them specially sensitive to the action of light. In the treatment, therefore, of alcoholic amblyopia, especially in all its forms be forbidden, but the eyes should be protected constantly against the light, and particularly against the ultra-violet rays.

91. **An Epidemic of Mild Jaundice.**

P. J. J. HONIG (*Nederl. Tijdschr. v. Geneesk.*, June 5th, 1926, p. 2347) alludes to the mild epidemic of Weil's disease reported by Körner (*Epitome*, August 22nd, 1925, para. 120) and describes an outbreak of 25 cases which occurred in the Dutch village of Zuenderdorf, which has a population of 400, between November, 1925, and March, 1926. Of the patients 14 were males and 11 females. Examination of the blood was made in 6 cases with negative results. Inoculation of guinea-pigs had no effect, and the blood serum did not agglutinate *Leptospira icterohaemorrhagiae*. The disease ran a very mild course, the jaundice as a rule disappearing within a fortnight. The occurrence of 25 cases within a few months suggested a local source of infection, but none could be found. In particular no spirochaetes could be detected in the ditch water near a school where most of the cases occurred.

92. **Urinary Complications of Pertussis.**

S. CANNATA (*La Pediatria*, June 15th, 1926, p. 663) draws attention to certain urinary complications which he has noted in a collection of some 600 cases of pertussis. Albuminuria of slight degree was frequent, especially in the early stages; it was usually transitory. Haematuria was rare; in 6 cases when the coughing attacks were very violent blood appeared in the urine. Slight and transient haemoglobinuria was seen in four cases. Acute glomerular nephritis was noted in 22 cases, and haemorrhagic nephritis in 4. Cystitis and pyelocystitis were found in 47 cases but disappeared eventually.

## Surgery.

93. **Treatment of Cerebral Tumours.**

R. LOZANO (*Rev. med. de Barcelona*, April, 1926, p. 352) reviews the literature and records his own experience of thirty-five patients with the diagnosis of cerebral tumour on whom he operated. In thirteen no tumour was found at the operation, and in one of these cases the necropsy confirmed the absence of a tumour, but showed a hydrocephalus of unusually large size. Two deaths occurred in Lozano's series—the first seventeen days and the second two months after the operation. In the last cases the necropsy showed an enormous hydrocephalus and a small tumour on the wall of the fourth ventricle. The subsequent history of the other patients was not known, with three exceptions. The first, which was a case of posterior craniectomy for cerebellar tumour, survived for a few years with the symptoms attenuated but without recovery of vision. The second patient, who had a calcified tumour the size of a mandarin orange removed from the left frontal lobe, was completely cured, as the intense headache, epileptiform attacks, and mental disturbance had disappeared for two years. The third patient, who had been operated on for a cyst in the left parietal lobe, had been alive for six months after the operation with paresis of the limbs on the opposite side and difficulty in articulation, both of which were improving gradually.

94. **Adenoma of the Tongue.**

G. BOLOGNESI (*Studium*, March 20th, 1926, p. 119), who records an illustrative case, comes to the following conclusions: (1) Adenoma of the tongue is a very rare occurrence. (2) In the present state of our knowledge it is impossible to explain the rarity of this tumour, which originates from definite groups of mucous glands in the tongue, in contrast with the relative frequency of carcinoma of the tongue, which is constituted by embryonic elements. (3) Most of the cases described have occurred in the male sex. (4) The tumour may be found at the base of the tongue, the sides, the lower surface, or towards the tip. (5) The condition is most frequent in young persons, but Péan's and Bolognesi's cases were in patients over 50 years of age. (6) Adenoma of the tongue is a benign affection of slow growth, and in only exceptional cases does it grow to a size sufficient to cause mechanical disturbance of respiration, mastication, and deglutition. (7) Malignant degeneration is uncommon, being rarer than in adenomata situated elsewhere. (8) In structure the tumour is a tubular, follicular, or acinous adenoma. (9) Clinically adenoma of the tongue is a round or ovoid tumour, of moderate size, definite outline, of soft and elastic consistence, nodular surface, and freely movable beneath the mucous membrane of the tongue and on the sublingual muscular plane. (10) The differential diagnosis is comparatively easy: adenoma is distinguished from fibroma and lipoma chiefly by its consistence, surface, colour, and evolution, and from lingual goitre, which is situated at the base of the tongue and gives rise to serious symptoms.

284 B

95. **Treatment of Dislocations of the Patella.**

P. MALLET-GUY and J. ROLLET (*Rev. de Chir.*, No. 2, 1926, p. 105) state that dislocations of the patella may assert their presence at or shortly after birth, while in many cases they are not discovered for a considerable number of years after wards. Most of them are recognized, however, when the child begins to walk, and the patella becomes dislocated outwards over the external condyle when the knee is flexed. Sometimes the condition is produced as the result of an injury where the knee is suddenly and violently flexed. If treatment is not undertaken the dislocation becomes a more or less permanent condition with alteration in the surrounding structures and muscles. Numerous operations have been devised from time to time to deal with this deformity with various degrees of benefit. The authors have adopted the following method in the so-called old dislocations of the patella with success. A U-shaped incision is employed extending to below the anterior tuberosity of the tibia. After reflecting the skin the joint is opened on the outer side of the patella by incising the lateral expansion of the vasti and the capsule of the joint; if the synovial membrane is hypertrophied it is excised. The dislocation is then reduced and the patella can be easily placed in its normal position, the outer incision being enlarged if necessary. The tibial insertion of the quadriceps extensor is then transplanted to the inner side of the tibia in the usual way. To avoid the possibility of recurrence this is rather overdone than otherwise, and the capsule on the inner side of the patella is plicated. The opening in the joint to the outer side is closed by reflecting the fibrous periosteum from off the anterior surface of the patella, which is easily accomplished. Finally the skin is sutured in position. The patient walks two months later.

96. **Axillary Thrombosis treated by Phlebotomy.**

L. BAZY (*Bull. et Mém. Soc. Nat. de Chir.*, May 22nd, 1926, p. 529) records a case of thrombosis of the axillary vein treated by surgical operation with a most satisfactory result. The condition occurred in a man, aged 27, who was admitted to hospital with oedema, pain, and swelling in the arm following some violent muscular work ten days previously. There was no history of injury or disease to account for the symptoms, and the condition was diagnosed as a thrombosis of the vein. The vein was therefore exposed and opened and numerous clots evacuated, after which it was carefully sutured. After the operation there was a rapid return to the normal. Operative treatment appeared the only course possible in this case in view of the increasing intensity of the swelling and pain in the arm, and was justified by the result. The etiology of the condition is uncertain; there was no evidence of tubercle or syphilis, while cultures taken from the wound proved negative. The only possible explanation was that the condition was due to the excessive muscular action of the limb shortly before the onset of the symptoms.

97. **Cautery Circumcision.**

I. G. DUNCAN (*Urol. and Cut. Rev.*, April, 1926, p. 195), in cases of chancre, chancroid, and neglected gonorrhoea complicated by balanoposthitis, has recently been employing circumcision by cautery. The principal points of difference from the ordinary method are as follows: (1) A catheter is tied round the penis as close to the abdominal wall as possible, and novocain is injected just anterior to the catheter instead of at the site of incision. (2) The incision is made through healthy tissue, all the infected area being excised, so as to prevent the leaving of any folds or pockets which might harbour infection. (3) The entire area of raw surface is lightly touched with a cautery, special attention being paid to the margins of skin and mucous membrane, and to any bleeding vessels, or any ulcer on the glans penis. (4) No ligatures or sutures are used. (5) After the denuded surface has been sponged with alcohol it is dressed with an alcoholic solution of picric acid, and afterwards with Ochsner's solution. The cases usually heal in three or four weeks.

98. **Intussusception Statistics.**

W. F. SUERMONDT (*Nederl. Tijdschr. v. Geneesk.*, April 10th, 1926, p. 1524) reports that 40 cases of intussusception were treated at the surgical clinic at Leyden from 1908 to February 15th, 1926, with 15 deaths, and a mortality of 37.5 per cent.; 27 were boys and 23 girls. One infant was aged 2 months, two 3 months, four 4 months, four 5 months, four 6 months, three 7 months, two 8 months, three 9 months, two 10 months, two 11 months, four 12 months, one 15 months, one 16 months, two 18 months, and five 2 years or over. In 3 there was a colo-colic intussusception, in 2 an enteric intussusception, and 35 were examples of the ileo-caecal form. In 2 there was a polypus of the small intestine, and 2 patients had purpura. In 29 the intussusception could be felt before the operation. In 5 cases, which were all fatal, the intussusception could

be felt per rectum. In another 4 cases which did not survive a fistula was made in the everted appendix, owing to paralytic ileus. In 25 cases, of which 5 were fatal, the intussusception was reduced and appendicectomy performed. Reduction of the intussusception alone was performed in 4 cases with 3 deaths. Resection was carried out in 10 cases with 4 deaths. The average duration of stay in hospital after operation was sixteen days. Closure of the appendix fistula had naturally not taken place by the end of this time, but occurred some months later. The causes of death in Auesen's series were as follows: peritonitis, 6 cases; intoxication due to the long duration of the intestinal obstruction 7 cases; pneumonia two days after the operation, 1 case. The mortality of cases operated on after twenty-four hours (30 per cent.) was more than three times as high as in those operated on within twenty-four hours (6.3 per cent.). Sacromont maintains that valuable time should not be lost in attempting to reduce the intussusception by bloodless means. In the ileo-caecal form reduction of the intussusception should be followed by appendicectomy. In the ileo-faecal and colic-ecolic forms reduction of the intussusception only should be performed. When the condition of the gut is bad, it is better to perform resection than run the risk of late perforation of the intestine due to gangrene.

### 99. Treatment of Carpal Ganglia.

J. J. GINSBURG (*Zentralbl. f. Chir.*, May 8th, 1926, p. 1176) recommends the modern practice of radical extirpation of carpal ganglia. Recurrences are found, according to different authorities, in from 3 to 30 per cent. of the cases. The author states that these cysts may be classified according as they arise from the joints, the tendons, or the periosteum. Some writers hold that ganglia originate in a colloidal neoplasm of the connective tissue and are unilocular or multilocular, according to their position and anatomical relations. Others hold that these cysts are of traumatic origin, with subsequent blood effusion. Endarteritis in the vicinity of the cyst has been described. Some ganglia appear to originate in colloidal degeneration of the capsular ligament or of the tendon sheaths, with secondary atrophy and cyst formation; these are primarily unilocular and subsequently become multilocular. Ginsburg recommends transverse incision of the skin and cyst wall, followed by careful removal of the lining membrane. Mature ganglia are dissected out more readily than those that are immature.

### 100. The Complications of Gastro-enterostomy.

HARTMANN (*Bull. et Mém. Soc. Nat. de Chir.*, April 3rd, 1926, p. 372), discussing the after-results of gastro-enterostomy, finds that most of the post-operative complications are the result of infection of the stomach wall. The presence of organisms in the ulcers themselves has been established by Rosenow. Hartmann found organisms present in the stomach wall some distance from the ulcer, and has confirmed this by the removal of fragments of mucosa at operation. He has encountered five cases of vicious circle, three following anterior and two posterior gastro-enterostomy. Two of these patients were relieved by an anastomosis between the ascending and descending limbs. He thinks that reflex bilious vomiting is not a true vicious circle; it may arise as the result of a localized peritonitis below the mesocolon. It usually subsides after a few days, when the peritoneal irritation settles down. Acute gastric dilatation following operation is probably due to paresis of the stomach and not to infection. It can generally be relieved by gastric lavage. Necropsies have not revealed peritonitis in these cases. The cause of gastro-jejunal ulceration still remains obscure, although it has been shown to be the result of the prolonged effect of the acid gastric juice on the jejunal mucosa.

## Therapeutics.

### 101. The Employment of Vaso-dilators in Hyperplezia.

C. MATTEI and J. DIAS-CAYARONI (*Rev. Méd. de l'Est*, March 1st, 1926, p. 149) record their researches on the effects of extract of mistletoe, sodium nitrite, and trinitrin in seven cases of hyperplezia. All the patients had a moderate degree of arterial hypertension without signs of secondary renal or cardiac disease. Prior to any medicinal treatment every patient was kept in bed on a diet of milk and vegetables, and their blood pressures were recorded at regular intervals during the twenty-four hours for several days. The majority of the patients, after two days' rest, showed a spontaneous and definite fall of blood pressure, more marked in the maximal than in the minimal pressures. The extract of mistletoe was given by intramuscular injection (5 cg. night and morning) and in pills (15 cg. night and morning) for four days. The latter acted more slowly and in a lesser degree, but

otherwise their effect was similar to that of the intramuscular injections, which produced a regular fall of maximal temperature, beginning ten minutes after the injection and exhibiting its greatest effect one hour later. When treatment was discontinued the blood pressure began to rise on the next day, and six days later the blood pressure had returned to its former height. Sodium nitrite (0.25 cg.) in solution given at 10 a.m. and 6 p.m. for four days produced a rise of maximal pressure during the first forty-eight hours; in one case this amounted to 30 mm. above the maximum pressure observed prior to any treatment. On the third and fourth days there was no rise, but a lowering of the maximal pressure (averaging 20 mm.) began in ten minutes and reached its lowest point thirty to sixty minutes after the dose had been taken. There was no variation of minimal pressure, and on the first day after the cessation of treatment the blood pressure rose to its original figure. Every dose produced tachycardia. Trinitrin was administered to patients who had failed to respond to rest and dietetic treatment. It produced an initial rise followed by a more marked fall (20 to 40 mm. Hg) in ten to twenty minutes after ingestion. Two hours later the maximal pressure was frequently higher than before commencement of treatment. The authors conclude that sodium nitrite is useless and dangerous, and trinitrin is uncertain and transient in action. Both produce tachycardia without definite reduction of blood pressure. Mistletoe is the most reliable agent in reducing the maximum pressure during and for a few days after cessation of treatment. It is less reliable in regard to minimal pressure, but it appears to reduce the force of the ventricular systole as the systolic pressure falls. This partial result is not accompanied by a similar reduction of minimal pressure, which might induce sleep. In every case the maximal and minimal pressures returned to the original scale within a few days of the cessation of treatment.

### 102. Treatment of Anaemia.

N. B. EDDY and A. W. DOWNS (*Canadian Med. Assoc. Journ.*, April, 1926, p. 391) urge the importance of diet in treating anaemia in view of its value in blood regeneration. The dietary factors favouring the production of erythrocytes and haemoglobin, arranged in order of their beneficial influence, have been found to be (1) cooked beef liver, (2) lean beef, (3) beef heart, (4) spinach and beet tops, (5) fruits and other green vegetables. Arsenic and the American remedy germanium dioxide were found to be inert, but iron was beneficial when the supply of it in the body had been exhausted. In many cases of secondary anaemia the oral administration of a combination of dried powdered spleen and red bone marrow gave good results, and the subcutaneous injection of small doses of secretin was also found to increase the numbers of both red and white corpuscles. The authors add that, although liquid preparations of secretin do not keep good for more than a few days, a satisfactory dried powder can be readily obtained which keeps well, is very soluble, and its aqueous solution can be easily sterilized.

### 103. Ergotamine Tartrate in Obstetrics.

C. J. GREMMÉE (*Nederl. Tijdschr. v. Geneesk.*, April 3rd, 1926, p. 1387) states that ergotamine tartrate is a reliable drug which has a stronger action than other preparations of ergot and does not give rise to any infiltration after injection. It has chiefly been used in Swiss clinics, where it has been found that the dose of 1 c.cm. originally recommended is too high and has been reduced to 1/2 c.cm. In labour it should be used only during the third stage, when it is said to be extremely valuable for haemorrhage due to uterine atony, and it is also useful for subinvolution. In the puerperium it is indicated when it is not certain whether the membranes have been completely expelled and involution is not complete. In such cases 1/2 c.cm. is injected daily intramuscularly.

### Acriflavine in Gonorrhoea.

R. DUHOT (*Le Scalpel*, March 20th, 1926, p. 253) observes that the various local methods of treating gonorrhoea during the last thirty-five years have proved to be of uncertain value. Many investigators have therefore tried the intravenous route, and Duhot reported in 1912 that some syphilitic patients, suffering also from gonorrhoea, were cured of the latter after injections of neosalvarsan. Systematic injections of neosalvarsan, however, failed to cure acute gonorrhoea. Of other chemical substances similarly used the most efficacious is said to be acriflavine (see *Epitome*, June 12th, 1926, para. 593), which is a powerful yellow dye, fluorescent in solution, which has been used for urethral injections for several years, but has only recently been injected intravenously. The author quotes Jausion's statistics, which he has been able to confirm in his own practice. Jausion's method is as follows: A 2 per cent. solution of acriflavine is injected on alternate days until cure is effected. The dose is 5 c.cm., which may be

given daily during the first two or three days if abortive treatment be desired. Jausion discards all local treatment, but Duhot reinforces these injections with prolonged irrigation of weak potassium permanganate. Acriflavine stains the skin and linen a deep yellow colour, but this discoloration can be removed by slightly acid methyl alcohol. Some patients suffer from slight shock, accompanied by a sensation of heat and a bitter taste in the throat; and occasionally there is a sensation of weight in the injected arm a few hours after the injection. The solution is caustic, and therefore it may produce endophlebitis, or inflammatory nodules at the site of the injections. Duhot uses a 10 c.cm. syringe half-full of the acriflavine solution, which is neutralized by completely filling the syringe with venous blood. This is slowly injected into the vein, fresh blood being drawn into the syringe and reinjected repeatedly. Jausion has treated 165 patients, and of these 153 appear to have been cured. It is claimed that this treatment, by carrying the disinfectant in the blood stream, is much more efficacious than any local injections or applications. Duhot states that he has treated 56 patients. Of these, 44 had simple acute or subacute gonorrhoea, while 12 were chronic cases with orchitis, prostatitis, etc. The total number of injections given was 664 and the treatment failed in 2 cases. In some cases six injections sufficed, while in others twenty or twenty-five injections were required.

#### 105. Expectant Treatment of Diphtherial Laryngitis.

E. BURGHARD (*Monatsschr. f. Kinderheilk.*, March, 1926, p. 626), from his experience of 70 cases of diphtherial laryngeal stenosis in Schlossmann's clinic at Düsseldorf, maintains that operation should be avoided as much as possible in laryngeal diphtheria, though not absolutely abandoned, as he claims that this is the best means of reducing the number of fatal cases. Expectant treatment should consist in the administration of antitoxin, large doses of narcotics until the membrane has become loosened, free supply of fresh air, the bed being kept close to the open window, and the avoidance of local treatment, steam tents, and inhalations, which serve only to frighten the child. Tracheotomy should only be performed when there is a sudden mechanical obstruction to the larynx and in those cases where there is any doubt as to whether there is a descending process. The operation should not be performed in mild and moderately severe cases, in cases of descending croup, and those accompanied by pneumonia, in infants owing to the bad prognosis at this age, and in influenza stenosis.

#### 106. Treatment of Strophulus.

P. VALLERY-RADOT and P. BLAMOUTIER (*Paris méd.*, April 24th, 1926, p. 398) during the last eighteen months have treated children suffering from strophulus, otherwise known as acute simple prurigo (Brocq), by oral administration of peptone one hour before meals. As the number of meals has to be reduced to four daily this method is inapplicable under the age of 1 year. From this period up to the age of 30 months four meals should be given daily—namely, at 8 a.m., noon, 4 p.m., and 8 p.m. No food should be taken between meals. After the age of 30 months only three meals should be given daily—namely, at 8 a.m., 1 p.m., and 7 p.m. The treatment should not be continued for too long a period. The best plan is to give the peptone for ten consecutive days, omit it for five days, and then give it for another ten days. A diminution in the number of the papules and vesicles occurs after a few days' treatment, but a relapse is liable to follow if the treatment is discontinued. The peptone therefore should be given until a month after complete disappearance of the eruption. The authors, who have successively employed meat peptone, bivalent peptone (meat and fish peptone), and a preparation containing in addition to meat and fish peptone extracts of egg and milk, find that the best, most rapid, and permanent results are obtained by the last preparation. The peptone is best given in the form of granules, a teaspoonful being administered one hour before each meal. Out of twenty cases so treated sixteen showed good results, while in four the results were not so good owing to the occurrence of relapses.

## Neurology and Psychology.

#### 107. The Transmission of Nervous Impulses.

F. BREMER (*Le Scalpel*, June 12th, 1926, p. 520) states that the investigations of numerous observers during the last twenty-five years have shown that a nervous impulse is only one form of very rapid protoplasmic transmission. The laws which govern its transmission in the peripheral nerves are those general biological laws which apply to all waves of stimulation (muscular, ciliary, etc.). Although the physico-chemical source of nervous impulses is still unknown, yet

these impulses belong to the group of stimuli which depend for their transmission only on the energy furnished locally by the medium which they traverse, as is the case of a wave of flame in a train of gunpowder. Nervous impulses resemble explosions, and this explains the fact that there is no relation between their energy and that of the stimulus. The energy of the impulse, which depends thus on that of the nerve fibre, is probably of the electro-chemical order; the part played by electrical energy in the stimulation, transmission, modification, and arrest of the wave of nervous impulse is well known. The nerve impulse, like all waves of stimulation, is manifested by a wave of negative electricity, with which it is probably identical. The most satisfactory hypothesis explaining all the features of nerve transmission is that the wave of functional negativity, apparently identical with the wave of stimulation, arises from a local and transitory depolarization of the nerve fibre at the point where the stimulus is applied; the resultant electric current acts in its turn as a stimulus throughout the length of the fibre, giving rise to a new negative wave which is transmitted from stage to stage. Conduction in reflex arcs and, generally speaking, in the grey matter, is regulated by more complex laws, possibly due to the structural complexity of the central nervous system, and not to the intervention of other processes.

#### 108. The Pseudo-bulbar Syndrome.

L. NEUBERGER (*La Vie Méd.*, June 4th, 1926, p. 1061) describes the distinctions between the pseudo-bulbar syndrome and glosso-labio-laryngeal paralysis; the latter marks the terminal stage in the majority of medullary lesions, and is due to bulbar lesions, involving the cranial nerve nuclei, while the pseudo-bulbar or glosso-labio-cerebral paralysis is due to lesions in the mesencephalon, chiefly in the basal nuclei. Consequently it is classed among the encephalopathies due to multiple and especially subcortical lesions. The facial changes due to pseudo-bulbar paralysis are of importance in its diagnosis. The characteristic emotional disturbances can be interpreted only by reference to the cerebral physiology. Apart from the subcortical psychomotor path, which is chiefly concerned in the synthesis and distribution of intellectual functions, there is another entirely distinct path for the development and expression of emotions. The upper stage, in the neighbourhood of the Rolandic area, is the centre for psychic elaboration; it is linked with the middle stage by the cortico-thalamic fibres. The middle stage is in the thalamic area, and here emotive organization occurs; it is probably also the controlling centre of the sympathetic system. The inferior stage includes the whole of the bulbar nuclei which control articulation and expression of emotive states through the laryngeal and facial muscles. Pseudo-bulbar paralysis supervenes in a number of circumscribed encephalopathies due in part to cellular lesions and in part to vascular degenerations which often result from cerebral arterio-sclerosis or thrombosis. These lesions may produce a secondary ascending degeneration extending to the cortex and resulting in progressive motor or psychic enfeeblement; when the lesions occupy the opto-striate region changes in the facial expression are more obvious than emotional instability. This alteration in the facial expression constitutes the "pseudo-bulbar mask." The features are immobile and expressive of surprise and anxiety, the face is haggard, the eyes fixed, speech monotonous, lips parietic, so that saliva escapes involuntarily; the head is bowed, movements slow, and a nasal dysarthria and dysphagia supervene. The diagnosis of pseudo-bulbar paralysis may be confirmed by observing the gait, the patient walking with short steps.

#### 109. Post-encephalitic Perversions.

G. HEUYER (*Arch. de méd. des enf.*, May, 1926, p. 249) remarks that post-encephalitic perversions are much commoner in the child than in the adult. In the latter epidemic encephalitis assumes, as a rule, a neurological form, and when psychical disturbances are present they are of the nature of confusion or dementia, are more psychomotor than psychical, and very rarely take on the form of perversions. The perversions observed in the child are of two types. As a rule they are characterized by suddenness, impulsiveness, lack of restraint, turbulence, fugues, thefts, and violence. These reactions resemble those of epilepsy in their content and form, but are distinguished therefrom by being conscious and not accompanied by loss of memory. Sometimes, however, the perversions bear the mark of reflection and premeditation like constitutional instinctive perverseness. In all cases the characteristic feature of post-encephalitic perversions is the failure of intimidation to act upon them and the impossibility of affecting them by blame or punishment. Heuyer maintains that the perversions are not a sequel but a clinical form of the disease, as is shown, not only by examination of the cerebro-spinal fluid, which presents a distinct excess of

engar, but also by clinical considerations. Three of Henyer's patients were subjects of Parkinsonism, which is a clinical form of the disease rather than a sequel. As regards treatment Henyer recommends the internment of such cases in an asylum without allowing them to mix with other patients, as the disease is still active, and it is probable, if not certain, that whether they show symptoms of Parkinsonism or not they are still contagious.

#### 110. Non-progressive Syphilitic Dementia.

L. MARCHAND, N. ANILY, and J. BAUER (*Presse Méd.*, March 16th, 1925, p. 308) state that since the discovery in 1857 by Esmerich and Jensen of the role of syphilis in the etiology of general paralysis several writers have maintained that the same cause might be responsible for non-progressive conditions of dementia to which they give the name of "syphilitic dementia." Some of these cases are merely examples of general paralysis of a sluggish or even stationary character, as is proved by post-mortem examination. In others the clinical picture is that of a hebephreno-katatonic syndrome, of which two varieties may be described, according as the dementia is associated or not with signs of neurosyphilis. Transitional forms may also be observed.

### Obstetrics and Gynaecology.

#### 111. Morphine and Ether Injections during Childbirth.

A. ECKE and R. TAUBERT (*Zentralbl. f. Gynäk.*, April 24th, 1925, p. 1111) have had favourable results from using Grathney's method of inducing anaesthesia during labour. They find that the subcutaneous injection of morphine and magnesium sulphate must be given when the external os will admit two fingers and the uterine contractions are regular and strong; in primiparae the head should have engaged in the pelvic brim. Later, when the os is of "stepping" dimensions, the rectal injection of ether and alcohol mixed with oil is given. There is no danger to the mother, but the continuous presence of the physician is required. In more than 125 cases the authors had no foetal deaths, but some degree of asphyxia neonatorum was almost constantly encountered, responding to the usual treatments. The course of labour is somewhat slowed and bladder trouble is apt to occur as a sequel; further analgesic procedures are required for suture of the perineum. The method is contraindicated in high degrees of pelvic contraction, pyrexia during labour, and abnormal positions of the foetus. It was unsuccessful in 15 per cent. of the authors' cases and usually in obese patients; only 5 per cent. required the application of forceps. The anaesthesia lasts no longer than four to six hours; anaesthesia is usually complete.

#### 112. Pelvic Sympathectomy.

A. HAMANT (*Bull. Soc. d'Obst. et de Gynéc. de Paris*, March, 1926, p. 189) describes his experience of resection of the pelvic sympathetic nerves. He remarks that excision of the internal iliac sheath on both sides is an operation which may present considerable difficulty in fat subjects with a thick mesosigmoid; resection of the presacral nerve which joins the lumbar and hypogastric ganglia and lies in front of the fifth lumbar vertebra on the left iliac vein is simpler and more speedy and is the operation of choice. These operations have been done by the author in three and fifteen cases respectively; the patients had with one exception sclerotic ovaries, and had complained of severe intractable pelvic pain, especially in association with the menses. In the majority of the operations sympathectomy was combined with coniform excision of a portion of one or both ovaries, puncture of the cysts, appendectomy or ligamentopexy, but the author attributes the post-operative disappearance of the pain very largely to the operation on the nerves; eighteen months is the longest period which has elapsed since operation. As regards the sequels of the sympathetic nerve division it was noted that the next menstruation, whatever the interval since the last, always followed within two to three days, and that succeeding menstruations were regular and became established without pain. Micturition was often unmodified, but transitory incontinence followed in one and frequency in several cases. Rectal functions during convalescence appeared to have been favourably affected by the operation.

#### 113. Induction of Premature Labour in Pyelonephritis.

SCHOCKAERT (*Druzelles Méd.*, May 2nd, 1926, p. 798) describes two cases of severe pyelonephritis in pregnant women necessitating the induction of premature labour. The first patient, aged 50, had had one child six years earlier and a miscarriage one year before her third pregnancy; the second patient was a primipara, aged 20. Both patients had a severe *B. coli* infection of the right renal pelvis; vaccines and

medicinal treatment gave only temporary relief, and as the patients had pyrexia accompanied by rapid emaciation, and complete anorexia, Krause's method of induction of labour, under strict antiseptic precautions, was employed in both cases. Both children were born alive, at seven and a half months, but the second died eight hours after birth. A hypodermic injection of pituitrin and small doses of quinine half-hourly accelerated labour in the second case. Rapid improvement with disappearance of *B. coli* from the urine followed delivery in the first case, but in the second, bacilluria, though diminishing under vaccine treatment and urinary antiseptics, still persisted.

#### 114. Subcutaneous Symphysiotomy.

S. G. MARRUZ (*Rev. de med. y cir. de la Habana*, March 25th, 1926, p. 175) records a case of breech presentation in a primipara, aged 42, successfully treated by subcutaneous symphysiotomy followed by episiotomy, which is the first example on record of petriotomy being employed for a disproportionate size of the pelvic extremity. He states that owing to the adoption of the subcutaneous method, symphysiotomy, which had lost much prestige, has recently recovered a good deal of its former reputation, so that, if necessary, it has become an operation which can be performed in the patient's house without having to remove her to a clinic. During the last two years Marruz has employed the method recommended by Ortiz Pérez, who uses a special curved bistoury. The subcutaneous method of symphysiotomy was originally introduced by Cannival of Utrera in Spain, and dates from the year 1777. The vicissitudes which symphysiotomy has undergone since then are due, not to the operation itself, which is a rational and physiological one, but to defects of technique, and especially to the lack of a clear idea as to the cases in which it is indicated.

#### 115. The Sedimentation Test in Gynaecology.

D. D. TROUBITSINE (*Rev. Franco-Russe de méd. et de biol.*, March, 1926, p. 3), as the result of the study of the sedimentation rate of the red corpuscles in 1,158 women, of whom 70 were in normal health, 92 were pregnant, and the rest suffering from various gynaecological conditions, came to the following conclusions: (1) The sedimentation rate is not a specific reaction for a definite affection. (2) The causes of rapid sedimentation being found in various gynaecological affections, the sedimentation rate has no diagnostic importance. (3) The sedimentation rate may be regarded as a criterion of health and disease and as an indication as to the time for surgical intervention; a slow sedimentation rate is a guarantee of a healthy condition of the organism, while rapid sedimentation is a sign of a morbid state without indicating its nature. (4) There is no definite relation between the duration of sedimentation on the one hand and the number of leucocytes, red cells, quantity of haemoglobin, duration of coagulation, and amount of chlorides in the blood on the other.

#### 116. Diathermy Treatment of Gonorrhoea in Women.

MME SOUZAN (*La Gynéc.*, February, 1926, p. 65) speaks favourably of diathermy in the treatment of chronic gonorrhoea in the female, and records illustrative cases, including one of bilateral salpingitis. She recommends dorsal and ventral application of indifferent electrodes and the special vaginal or urethral electrode of Roucayrol; at each sitting, which should last at least twenty minutes, a temperature of 45°C. or rarely 46° to 48° is reached. The treatment is usually daily, but in acute cases has sometimes been given at twelve-hourly intervals. Twelve to twenty sittings are required, and the patients should be warned to expect after the first few an increase of the discharge. Treatment is followed by a polymorpholeucocytosis including many young forms, and it is to this rather than heat engendered locally that Roucayrol ascribes the beneficial effects.

#### 117. Treatment of Severe Uterine Haemorrhage.

G. BAKSCHT (*Zentralbl. f. Gynäk.*, May 22nd, 1926, p. 1390) recommends injection of the patient's haemolysed blood in severe uterine haemorrhage occurring in the absence of gross uterine disease. Into a syringe containing 6 c.cm. of distilled water, 14 c.cm. of blood are introduced from a vein of the arm, and, after shaking, the haemolysed mixture is injected into the gluteal muscles. Two to five injections at one to two days' intervals are usually found to be effective in stopping the bleeding, but another course may be necessary some months later. Five cases of profuse haemorrhage endangering life are recorded in which this treatment appeared very successful; they include one of menorrhagia of puberty, one in which an ovary was cystic, and one in which the adnexa were fixed. The treatment is thought to be effective by reason of the stimulating effect exercised by the products of haemolysis on the vegetative nervous system and the vasomotor centre.

## Pathology.

**118. The Pathogenicity of *B. rhusiopathiae suis* for Man.**  
C. POSTMA (*Nederl. Tijdschr. v. Geneesk.*, February 20th, 1926, p. 754) states that the *Bacillus rhusiopathiae suis*, the organism of swine erysipelas, was regarded as quite harmless for man until Casper, Hildebrand, and Meyer, in 1899, almost simultaneously described a dermatitis occurring in veterinary surgeons due to infection with cultures of this organism during protective inoculation of pigs against swine erysipelas. The disease was subsequently shown to be caused in man by injuries during inspection of meat, in slaughterers, and in those carrying infected animals. After an incubation period of one to four days the wound, which is usually on the hands, begins to itch and burn, and a bluish-red swelling soon appears. The joints of the affected part are swollen, active movements are impossible, and passive movements difficult. Suppuration does not occur, but vesicles frequently form. Local recurrence after recovery often takes place. Lymphangitis, occasionally accompanied by lymphadenitis, is sometimes noted. The disease usually runs a chronic or subchronic course. The history of infection, prolonged course, the failure of surgical measures or external applications, and the prompt reaction to specific serum usually enable a diagnosis to be made without bacteriological examination. *B. rhusiopathiae suis*, however, has frequently been found, especially at the margin of the lesions. While in untreated cases the disease lasts from three to six weeks, according to the severity of the attack, injection of the specific serum (2 c.cm. per 10 kilos of body weight) usually causes relief in twenty-four hours and a cure in forty-eight hours. Repetition of the injection is rarely necessary. The local dermatitis described by Rosenbach in 1844 under the name of erysipeloid as occurring in cooks, poulterers, slaughterers, and farmers, appears to be bacteriologically and clinically closely allied with swine erysipelas, the differences being explained by variations in virulence of the organism.

**119. The Active Principle in Tuberculin.**  
E. R. LONG and FLORENCE B. SEIBERT (*Amer. Rev. of Tuberculosis*, May, 1926, p. 393) report a series of experiments which appear to indicate that the principle in tuberculin which causes a skin reaction in tuberculous subjects is of protein nature, since it is completely precipitated by ammonium sulphate, while nearly all other protein precipitants throw it out of solution to some extent. It does not dialyse and is not found when all protein has been removed. It loses its activity when treated with pepsins in acid solution or alkaline trypsin, while acids or alkalis of similar strength, and erepsin or trypsin in neutral solutions, do not materially reduce its activity. It has been prepared in a crystalline form, which takes the methylene blue stain, gives the biuret, Millon, and Molisch reactions, and produces a marked skin response in tuberculous guinea-pigs, normal animals being unaffected by it.

**120. The Ferment Content of the Serum in and apart from Pregnancy.**  
E. HERRMANN and F. KORNFELD (*Wien. Arch. f. inn. Med.*, April, 1926, p. 469) examined the lipase and diastase content of the serum in eight non-pregnant women, eight in the early months of pregnancy, nineteen in the last months, and eight at the menopause, with the following results. As regards lipase, non-pregnant women showed the highest values in the intermenstrual period, the lowest just before or just after menstruation. In pregnant women there was a pronounced fall at the beginning of pregnancy, followed by a slow rise as pregnancy advanced, without, however, reaching the normal level. During the menopause the lipase values were low, though not so low as in the early stage of pregnancy. As regards diastase, non-pregnant women showed the lowest values in the intermenstrual period, and the highest just before or just after menstruation. Pregnant women showed a marked rise at the beginning of pregnancy, followed by a slow fall, but the values remained higher than in the non-pregnant state. At the menopause the figures were approximately the same as at an advanced stage of pregnancy.

**121. The Mechanism of Cancer Metastasis.**  
As the result of experimental work M. T. BURROWS (*Arch. Intern. Med.*, April 15th, 1926, p. 453) believes that cancer may result from primary crowding of cells and a relative reduction of the blood supply. The cancer cell is not different from the normal cell, but is merely a normal cell reacting to limitation of movement and cell crowding. The reactions which these cells undergo are said to be the result of a gradual accumulation of a substance or substances termed the "archusia," which is formed only in the presence of nutrient substances and oxygen. The process of growth is not merely the result of the action of the "archusia," but depends on the presence

of other food substances in the medium. In low concentrations the "archusia" has no effect; in medium concentrations it causes cell migration into a solid protein medium and towards larger droplets of fat; in all higher concentrations the cells themselves are digested. Cancer metastases are not, he thinks, the result of simple migration of cancer cells to distant organs; they are the result of the spread of a liquid substance from the main tumours which is liberated by the digestion of the central cells of the cancer. This digestion is not an autolysis resulting from absence of oxygen, but the result of excess of growth-stimulating substance, a product of cell oxidation. This fluid stimulates the growth of both cancer cells and of normal cells. The former, already adapted to it, respond more quickly; they rob normal cells of their nutrition and so destroy them. Normal tissue may undergo malignant transformation as the result of prolonged action of this fluid. Burrows considers that while these observations throw light on the mechanism of cancer metastasis they indicate the cause of cancer. Cancer may be induced by a number of substances or conditions, such as coal tar and other lipid solvents, bacteria, animal parasites, x rays, radium, and arsenic. It is a senile disease, and may result from the action of any of the above, but it also occurs in congenital tumours and defects, in chronic inflammatory areas, in tissues suffering from senile atrophy, and in tissues atrophied by various external factors, such as exposure to sun or weather. Cancer, he concludes, is not the result of any specific substance, but of a primary change, either in the cell or the tissue, induced by any one of the above. The process can, he adds, be reproduced experimentally by reducing the blood supply and causing the cells to revert from the differentiated to the growing state.

**122. The Fate of Red Blood Corpuscles.**  
C. A. DOAN and FLORENCE R. SABIN (*Journ. Exper. Med.*, June, 1926, p. 839) have confirmed the discovery by Rous and Robertson that there is a constant fragmentation of red cells in the circulation of normal animals, and find that the debris thus produced, and even whole red cells, are taken up and destroyed by wandering endothelial phagocytes or clasmato-cytes. In pathological conditions involving increased fragmentation a corresponding increase in the desquamated endothelial cells of the blood stream and of the clasmato-cytes from the tissues was found to occur. The present authors claim to have been able to identify these cells and to distinguish between them and ordinary eosinophil leucocytes by the nature of their granules, their negative reaction to the peroxidase test, and by the type of their motility. They add that these cells only show a positive peroxidase reaction when they have ingested from the circulating blood substances which respond positively to the test. It is concluded that the desquamated endothelial cells in circulating blood include degenerating forms and also actively phagocytic cells. The authors have watched the process of breaking up of the red cells and the absorption of the fragments by the clasmato-cytes.

**123. Transmission of Typhoid Fever by Bed-bugs.**  
LYNN-GE (*Nat. Med. Journ. of China*, February, 1926, p. 62) has studied the possibility of the transmission of typhoid fever by bed-bugs. A special wooden cage was used framed with glass and covered with iron gauze for ventilation. The cage was divided into two parts by iron nets. In the first experiment a normal rat and a rat injected intraperitoneally with 0.5 or 1 c.cm. of an eighteen to twenty-four hours' broth culture of typhoid bacilli were kept separately and bed-bugs put in the infected part. The injected rat usually died on the eighth or ninth day, and the normal rat died in the second or third week after infection. After death cultures were made and a necropsy performed. Of thirty rats exposed, fourteen (46.6 per cent.) became infected. Lynn-Ge thinks that two conditions are essential for the infection of the bed-bugs. First, the blood sucked by the bugs must contain a large number of typhoid bacilli. Secondly, numerous bugs must bite the healthy animal. In the second experiment four albino rats previously injected with T.A.B. vaccine, and three other rats injected with typhoid bacilli were put in the cage with the bugs. No rat died after two weeks. Fourteen rats recovered from typhoid fever were put into the cage with six other rats which had been injected with typhoid bacilli and observations were made for fifteen days, but no infected rat was found, probably owing to immunity from typhoid. In the third experiment the bugs were removed from the cage which contained the ten sick rats to a cage containing ten healthy animals. Only four of the latter became infected. In the fourth experiment cultures from the blood and intestines of bed-bugs which had been put on a sick rat for seven to eight days always showed typhoid bacilli. Lynn-Ge comes to the following conclusions: (1) Typhoid fever can be transmitted by bed-bugs. (2) Typhoid bacilli can be isolated from various parts of the bed-bugs.

## Medicine.

### 124. Lupus Vulgaris and Facial Erysipelas.

GECOFROT and MILLIOT, (*Bull. Soc. Française de Derm. et de Syph.*, May, 1926, p. 335) relate the case of a woman, aged 25, who had suffered for twenty years from non-ulcerating lupus vulgaris of the face, and of the nasal and buccal mucosa, which was slowly progressive and was invading the whole face. After a severe attack of facial erysipelas which subsided towards the eighth day and was followed by alopecia, there was a rapid extension of the lupous invasion, especially in the right submaxillary and the suboccipital regions, where the lupous patches were doubled in area. So far from erysipelas ameliorating the other disease it had actually produced exacerbation of the lupus. The patient improved under treatment with Vandromer's vaccine. Though erysipelas occasionally produces some improvement in cases of lupus, in others this does not occur or is only transient. In a case mentioned by Bazin ulcerative lupus of the nose healed, leaving an excellent scar, after an attack of facial erysipelas.

### 125. Cerebro-spinal Pressure in Cranial Trauma.

J. BEAUVY and DIAS CASTILHO (*Arch. de med. cir. y exp.*, May 29th, 1925, p. 323) records his observations on twenty cases of cranial trauma in which he measured the pressure of the cerebro-spinal fluid. His conclusions are as follows: In comparison of the first and second degrees the pressure of the cerebro-spinal fluid is increased, the lesions of the nerve elements proper being accompanied by rupture of the small vessels in the meningeal tissue and pia mater. The irritation produced by the small haemorrhages in the choroid plexus are sufficient to cause a rise of pressure owing to their increasing the secretion of the cerebro-spinal fluid. The prognosis of commotion of the first and second degrees is favourable as regards life. A decompressive operation is indicated, and the patients generally recover their normal condition in a short time. On the other hand, commotion of the third degree involves a gloomy prognosis, since there is also a considerable fall in the cerebro-spinal pressure. The question whether the fall in the cerebro-spinal pressure is accompanied by a fall in the peripheral venous and arterial pressures is now being investigated by the author.

### 126. Intradermal Reactions in Scarlet Fever and Measles.

S. DE VILLA (*La Pediatría*, May 1st, 1926, p. 467) has made a series of experiments, using the antigens of scarlet fever and measles. He found that neither cutaneous nor ocular reactions were of any use, and that intradermal reactions were nearly always negative in patients actually suffering from scarlet fever or measles. About 1,700 children were examined, and the results were 100 per cent. negative in children suffering from scarlet fever, 99 per cent. in convalescents, 100 per cent. in those vaccinated with antiscarlatinal vaccine, 92 per cent. in the newborn, 82 per cent. in nurslings up to 6 months, 64 per cent. from 6 to 12 months, 58 per cent. in 1 to 2 years, and 43 per cent. in those 2 to 12 years of age. A series of 50 nursing mothers and their children were tested at intervals of six months, and bore out the conclusions as to the relative immunity of mother and child. All the children vaccinated against scarlet fever gave negative reactions after intradermal injection. Similar observations were made in 102 cases of measles, with parallel results. The author adds that the reaction is not a diagnostic test of scarlet fever or measles, but a specific reaction as regards susceptibility to these diseases.

### 127. Relapsing Form of Pura Meningeal Spirochaetosis.

M. DEBRAY and JONESCO (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, May 27th, 1926, p. 831) record a case of meningitis in a woman, aged 23, who lived on the ground floor of a factory swarming with rats. The disease ran a favourable course and the patient recovered after nearly two months' illness. There were no clinical signs such as icterus or haemorrhages to suggest the spirochaetal origin of the symptoms, and it was only the remarkable relapsing character of the temperature that suggested the correct diagnosis. Inoculation of a guinea-pig with a centrifugized clot of urine obtained at three different stages of the disease caused death of the animal in eleven days with slight jaundice of the conjunctivae. On puncture of its heart directly after death large quantities of *Leptospira icterohaemorrhagiae* were found in the blood. Pettit's serum test was also definitely positive.

128.

### Differentiation of Herpes.

L. PATON (*Brit. Journ. of Ophthalmol.*, June, 1926, p. 305) distinguishes between herpes febrilis and herpes zoster. In the former the lesion follows the distribution of the nerve or nerves affected. There is always a preceding neuralgia, and the condition arises independently of any preceding disease. True skin is attacked, and permanent scarring is produced. One attack seems to confer immunity. The attack lasts three to four weeks and there follows a long period of diminished sensibility in the affected area. In herpes febrilis the distribution of the lesions may be irregular. There is no preceding neuralgia, and the condition may follow any infection producing a lowering of tissue resistance. The superficial dermis only is affected, and there are no permanent scars. There is a tendency to frequent relapses. The duration is variable and no impairment of sensibility is left.

### 129. Estimation of the Peripheral Venous Blood Pressure.

M. VILLARRET, M. MARTINY, and L. JUSTIN-BESANCON (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, June, 1926, p. 351) believe that the estimation of the peripheral venous blood pressure is of increasing importance. They discuss the various inaccurate methods employed hitherto and advise the use of the phlebo-piesometer. This is a manometer consisting of the ordinary V tube, fixed to a graduated scale; the shorter horizontal limb has an arrangement of valves regulating the flow of an anticoagulating solution from a reservoir fixed to the vertical support of the manometer. To the end of the horizontal limb is attached a rubber tube armed with a hollow needle, which is introduced into the median basilic vein just above the flexure of the elbow. The only disadvantage is that it is difficult to obtain serial readings; the authors have found, however, that when necessary the needle may be plugged and left in position and a second or third reading taken at intervals of fifteen or thirty minutes after the first by removing the plug and attaching the needle again to the instrument. The authors claim that their technique is less painful to the patient than an ordinary intravenous injection, and that any medical practitioner accustomed to perform intravenous injections can perform the necessary manipulations. The anticoagulant solution employed is prepared by dissolving 0.06 gram of sulpharsenol in 50 c.c.m. of distilled water; this solution is practically isotonic, and coagulation never occurs in the needle or tubes.

## Surgery.

### 130. Faecal Fistula following Acute Appendicitis.

AS J. B. DEVER (*Annals of Surgery*, June, 1926, p. 782) remarks, faecal fistula is one of the most unpleasant complications following acute appendicitis. A fistula from the large bowel will not impair health, but one high up in the small intestine will cause death from inanition. As a complication of appendicitis this condition is associated with the use of drainage and occurs especially where the appendix perforates near the caecum. Where the lower ileum is plastered down by adhesions Deaver advises an ileo-colostomy, which prevents obstruction and a faecal fistula. Faecal fistula occurred in 5 per cent. of cases of acute appendicitis, and of these 50 per cent. required operative repair. As a rule a test period for possible closure should be tried before operation is undertaken. In some cases simple inversion of the fistulous opening is sufficient. In others an ileo-colostomy is performed at the same time to short circuit the faecal stream. In extensive fistulae resection of the bowel may be necessary, including the lower ileum and caecum. Of 108 cases operated on 89 were discharged perfectly healed. In 10 there was a recurrence of the fistula, and some of these patients required further resection of the affected bowel before healing occurred.

131.

### Free Omental Grafts.

P. DUVAL (*Bull. et Mém. Soc. Nat. de Chir.*, May 15th, 1926, p. 492) discusses fourteen cases reported by M. J. Hertz in which free grafts taken from the great omentum had been used; in one case the result was inspected after a long interval of time had elapsed. In this case, operated on in 1923 for a fibroid and pelvic inflammation, a considerable portion of the sigmoid colon was found to be uncovered by peritoneum. This was covered by a free omental graft.

measuring 6 by 4 cm. More than a year later the abdomen had to be reopened, and it was then noted that the sigmoid appeared quite normal; it was completely covered by peritoneum, and there was no sign of adhesions. This result corresponds with what is found after similar experiments on animals. The grafts have been used in a variety of abdominal conditions, including appendicitis, pyosalpinx, and tuberculous peritonitis. In most of the cases the infection did not appear to be very virulent. The graft, however, will survive even in the presence of infection, though a satisfactory result cannot always be expected under such conditions. The operative results in the fourteen recorded cases were good.

### 132. The Increase in the Incidence of Cancer.

L. IMBERT (*Bull. de l'Assoc. Française pour l'Étude du Cancer*, April, 1926, p. 141) has tried to ascertain whether there is a real or only an apparent increase in cancer. He has reviewed statistically the cases of malignant disease found in a large hospital at Marseilles from 1870 to 1925: in the period 1871-75 there were 11 cases of cancer for each 1,000 admissions, and in 1920-24 40 cases per 1,000. He groups the location of the disease into old cases, such as tongue, uterus, vagina, and liver, which were recognized in the earlier period, and new cases, such as stomach and rectum, which are of more recent recognition. He finds the old cases show a decrease in the later years, while the new cases showed a steady increase. This is really due to the fact that these cases are more readily diagnosed at the present time. Cancer is comparatively rare before 30 years of age, and frequent after 50 years; it occurs most frequently from 50 to 60 years of age. The increase of cancer cases is, then, partly due to the increased age to which people now live and the larger number of older people in the world. The better diagnosis at the present time has also to be considered. The author concludes that while there is a real increase in the number of cancer cases this is actually due to the increased length of life.

### 133. "Snapping Shoulder."

H. A. GRUETER (*Zentralbl. f. Chir.*, May 22nd, 1926, p. 1303) describes the case of a railwayman, aged 44, who had noticed for three months a definite weakness in the right arm with pain and snapping sounds in the shoulder-joint when the limb was abducted beyond the horizontal; there was considerable wasting of the upper arm muscles. A skiagram showed a broad sessile collar-like bony projection on the outer surface of the humerus. At the operation this proved to be an exostosis springing from the humerus between the anterior border of the deltoid and the long head of the biceps. The exostosis was resected, the patient made a good recovery, and the pain and snapping in the joint disappeared.

## Therapeutics.

### 134. Therapeutic Value of the Double Salts of Caffeine.

M. GROSSMANN and K. LUSICKY (*Wien. klin. Woch.*, April 15th, 1926, p. 442) investigated the action of the double salts of caffeine (caffeine-sodium-benzoate and caffeine-sodium-salicylate) in ordinary doses on the pulse, blood pressure, respiration, and central nervous system in healthy persons and in those suffering from various diseases of the circulatory system. In many cases electro-cardiographic curves were taken at short intervals during the investigation, which lasted some hours. Subsequently larger doses were given by mouth, subcutaneously, intramuscularly, and intravenously. In intravenous injections the doses were as high as 0.8 gram, and in oral and subcutaneous administration 1.5 grams—in other words, considerably in excess of the normal. The result was that neither in healthy persons nor in those suffering from various circulatory diseases did the caffeine salts produce the slightest appreciable effect on the central nervous system or cardio-vascular apparatus. The authors conclude, therefore, that these salts should be abandoned in cases of collapse in favour of pure caffeine or black coffee.

### 135. A Synthetic Purgative.

M. EINHORN and H. A. RAFSKY (*Journ. Amer. Med. Assoc.*, June 5th, 1926, p. 1754) report successful results from the use of Isacen, or diacetyl-bisoxypheylisatin, a compound obtained by the acetylation of bisoxypheylisatin. This remedy was introduced by Guggenheim, who, after experimental work on the lines of Lenz, came to the conclusion that the action of such purgatives as senna and phenolphthalein depended on their degree of acidity and solubility. All similar combinations of which the acidity was less than that of phenolphthalein had a weaker stimulating effect on intestinal peristalsis, while those with greater acidity, up to a certain point, acted more strongly. He therefore produced synthetically

bisoxypheylisatin, which had a slightly higher acidity and a more pronounced laxative action; it caused, however, nausea and vomiting by inducing gastric peristalsis. He therefore improved it by the introduction of acetyl, which rendered it insoluble in the stomach. Isacen is insoluble in acids and water, and has no action until it comes into contact with the alkaline secretions of the duodenum, which set free the bisoxypheylisatin. The present authors have used the remedy in forty-seven cases of chronic constipation, occurring in patients aged from 60 upwards. Tablets containing 0.005 gram were given two to four times a day for a month, and in all but one case regularity of the bowels was obtained. All the patients were chronic invalids, suffering from such conditions as diabetes, chronic nephritis, paralysis agitans, general arterio-sclerosis, pulmonary tuberculosis, chronic myocarditis, and chronic gastritis. The authors conclude that this laxative will be of even greater value in healthy persons, and they suggest its trial for the routine treatment of constipation.

### 136. Paravertebral Alcohol Block in Cardiac Pain.

G. L. SWETLOW (*Amer. Heart Journ.*, April, 1926, p. 393) gives notes of eight patients with heart disease who suffered from attacks of severe precordial pain and in whom paravertebral alcohol injections of the dorsal root ganglia produced prompt relief. A dose of 5 to 8 c.cm. of an 85 per cent. solution of alcohol was injected as near as possible to each dorsal root ganglion chosen. With the patient completely flexed and lying on the side opposite to the one on which the injection was made the intercostal spaces to be injected are palpated and wheals of novocain are raised over the ribs above the spaces at a point 4 cm. from the mid-line. A needle 8 cm. long is introduced perpendicularly to the rib above the space and is directed downward, inward, and forward at an angle of 45 degrees, and advanced 2 cm. further from the lower border of the rib so that its point is between the internal and external intercostal muscles. By connecting the needle with a water manometer it is ascertained that it has not entered the pleural cavity as shown by the absence of extensive oscillations synchronous with respiration. Half of the 5 c.cm. of alcohol solution is then injected and the remainder is distributed by to-and-fro movement while the point is being withdrawn. By this means axonal degeneration of the thoracic nerve near the cell body is produced and some of the alcohol may reach the intervertebral foramen and act upon the ganglion. Freedom from pain after a single injection usually lasted several months and no complications or serious after-effects resulted. Swetlow claims that the procedure is simple and that it is based upon sound anatomical and neuro-physiological considerations.

### 137. Calcium Treatment as a Preliminary to Arsenobenzol Injections.

J. SCHUMACHER and W. LIESE (*Med. Klin.*, June 18th, 1926, p. 957) confirm previous observations that intravenous injections of calcium salts, either prior to or in conjunction with salvarsan administration, will prevent the toxic effects which are due to an excessive combination of salvarsan or neosalvarsan with the cellular protoplasm in the absence of an adequate quantity of calcium salts in the circulation. The authors have shown experimentally that calcium chloride, dissolved in distilled water or Ringer's solution, is as efficacious in the prevention of intoxication as are solutions of sodium arsenobenzol in the patient's serum. The favourable action of the serum solutions is due to the formation of colloid solutions, of sodium nucleinate and gelatin, from the contained proteins of the serum. The authors find that when neosalvarsan is to be administered the calcium chloride solution may be given by the mouth, but if salvarsan is employed it is necessary to inject the calcium chloride solution intravenously. There is evidence that strontium salts are even better than those of calcium.

### 138. Psoriasis treated with Bismuth.

A. VERSARI (*Rif. Med.*, May 3rd, 1926, p. 409) gives details of 21 cases of psoriasis treated by intramuscular injections of sodium potassium bismuthyl tartrate, which were given at intervals of five or six days, 2 to 3 c.cm. being given each time. In some cases a total quantity of 5 grams was given and was well tolerated. No local treatment was used. In 12 cases complete disappearance of the rash resulted, and in 4 cases of mixed psoriasis and syphilis much improvement occurred. In the remaining 9 cases the rash, desquamation, and hyperaemia were all lessened, but the rash did not entirely disappear. Relapses followed in all the cases except one, but the succeeding attacks were decidedly milder. The best results were observed in cases of generalized psoriasis. In one case the relapse did not occur until sixteen months after the injection treatment had been stopped.

328 C

dermatographia, urticarial crises, and stasis of the colon. Cure followed the administration of haemoglobin and supra-renal and mammary extracts, with lubrication and lavage of the intestine. A girl, aged 19, suffered from enormous mammary hypertrophy and periods of amenorrhoea; absence of the outer portions of the eyebrows, coldness, and a bluish appearance of the feet pointed to thyroid deficiency. Menstruation speedily reappeared after medication by thyroid and pituitary extracts. The patient became pregnant soon after marriage, but the enlargement of the breasts persisted. Another patient complained of violent pain in the pelvis and was found to have spasmodic retention of urine, with rapid pulse and hypermobility; a year previously she had been treated by x rays for dermatitis attributed to hyperthyroidism, and nine months' amenorrhoea had followed. The urgent symptoms yielded to treatment by potassium bromide and valerian, but eight days later a severe attack of double glaucoma occurred.

#### 145. Suprapubic Caesarean Section.

M. BROUHA (*Bruxelles Médical*, May 30th, 1926, p. 924) considers suprapubic Caesarean section less dangerous than the classical operation which it is destined to supersede. Before 1914 he performed the suprapubic operation occasionally; during the war he used it in 25 among 60 cases, and in the last year he has employed the suprapubic operation in every case. The advantages are: (1) a smaller incision; (2) there is no exteriorization of the uterus, and shock is lessened; (3) during the first few hours after operation the wound is less prone to disturbance, consequently the peritoneum heals well, with less risk of secondary infection; (4) if sepsis should occur the pelvic site of operation offers a better prospect of localization; (5) post-operative ileus, adhesions, or later, utero-parietal fistula, do not follow it; (6) a stronger scar than that after the classical operation is obtained. Brouha states that it has been proved that the risk of uterine rupture during later pregnancies or confinements is approximately one-tenth of that following the ordinary operation. While the latter may be very dangerous if performed when the patient has been subjected to previous manipulations the suprapubic operation is quite safe, thus allowing the treatment of contracted pelvis to be more obstetrical. The author believes that this test of labour in suitable cases may spare the mother a needless Caesarean section without greatly increasing the danger to the child. On the other hand, Caesarean section comes to aid the child in certain accidental complications of labour, such as an abnormally large foetus, prolapse of the cord, placenta praevia, and eclampsia. There will be, he thinks, in the future less hesitation to perform a relatively safe operation in order to save the child without lessening the mother's prospect of normal labours in future. Suprapubic Caesarean section is equally applicable in labour complicated by pelvic tumour preventing natural delivery.

### Pathology.

#### 146. Preparation of a Leprosy Vaccine.

J. HASSON (*Trans. Roy. Soc. Trop. Med. and Hygiene*, January, 1926, p. 349) describes a new method of diagnosing leprosy and of treating it by a vaccine. He states that the many specific remedies have yielded varying results in the hands of different observers, and suggests that these variations may be due to individual differences in the toxic and tegumentary evolution of leprosy as well as to personal idiosyncrasies in estimating the action of any medicament. Hasson therefore investigated the field of vaccine therapy and has prepared a specific vaccine, an autolysate, containing 15,000 million of *B. pyocyaneus* and 5,000 million of *B. leprae* in 2 c.c.m. of normal saline solution. The latter bacilli were obtained from different patients by the following method. Blisters were induced by carbon dioxide snow and the serum was removed from them after a period of twenty-four to thirty-six hours. This serum was mixed with that taken from other patients suffering from different forms of leprosy—nodular, anaesthetic, or mixed—and kept in the incubator at 36° C. for from fifty days to three months. A mixed culture of *B. pyocyaneus* was then added to the serum, which had previously been rendered inoculable by the addition of a sterile 2½ per cent. solution of sodium citrate. The whole was centrifuged for twenty minutes, the requisite quantity of distilled water added, the bacilli counted, and the vaccine put up in 2 c.c.m. ampoules. The author states that the solution must be at least fifty days old. The serum obtained from the blisters contained *B. leprae* even in cases in which the bacillus was not recovered from the usual situations; it therefore acts as a means of early diagnosis in leprosy. Hasson explains the action of the vaccine as being due to

the formation of antibodies by the bacilli themselves. The addition of an autolysate of *B. pyocyaneus* is made in order to induce in the patient an increase of temperature capable of dislodging the *B. leprae*.

#### 147. The Blood in Small-pox.

K. IKEDA (*Arch. Intern. Med.*, May 15th, 1926, p. 660) describes his observations on the blood in small-pox during a recent epidemic at Minneapolis. As the result of examination of about 200 cases he came to the following conclusions: (1) The earlier the rise of the platelets the sooner the approach of the desiccation period, indicating a shorter course of the disease. (2) Definite leucopenia during the maculo-papular stage indicates as a rule a mild discrete form. Progressive leucocytosis with an early high polynucleosis is the sign of a severe form. The higher the values the more probable the fatal outcome. (3) The early appearance of monoblasts, basophilic stippling, and polychromatophilia without obvious anaemia is an unfavourable sign, as it invariably means the purpuric form of small-pox. (4) Condensation and fragmentation of mature leucocytes are found only in the purpuric form, in which they appear comparatively early, and are usually associated with pathological normoblasts and basophilic stippling and polychromatophilia without visible anaemia. (5) A rapidly progressive absolute lymphocytosis is a constant characteristic of purpuric small-pox. (6) Scarlatinal and other exanthems, infectious purpura and toxic rashes with petechiae can be definitely differentiated from the purpuric form of small-pox during its erythematous stage by these blood findings.

#### 148. The Protective Power of the B.C.G. Strain of Tubercle Bacillus.

J.-F. HEYMANS (*C. R. Soc. de Biologie*, June 25th, 1926, p. 242) has tried to determine the value of the B.C.G. strain of tubercle bacillus in vaccinating against tuberculosis. Guinea-pigs and rabbits received intramuscular injections in the left thigh of a suspension of the vaccinating strain, and at intervals varying from ten days to six months afterwards a fully virulent bovine strain was injected intramuscularly into the right thigh, the dose of vaccine ranging from 1 to 50 mg. The infecting strain was cultured continuously *in vivo*, being transferred from one animal to another without intermediate culture on artificial media. A dose of 0.2 c.c.m. of a 1 per cent. suspension of the lumbar gland of an animal dying from it killed guinea-pigs regularly in thirty to forty days; doses even a thousand times smaller proved fatal, but only after a longer time. Examination of animals that received the living B.C.G. organisms without subsequent injection of virulent bacilli showed that, apart from a local lesion with some enlargement and necrosis of the focal glands after the larger doses, there was no evidence of tuberculosis; in other words, the living vaccine was borne without injury. The vaccinated animals that were tested with a virulent strain without exception developed tuberculosis; their survival time was, however, about twice that of the unvaccinated controls. Vaccinated animals kept with guinea-pigs suffering from open lesions also developed fatal tuberculosis. Heymans concludes that these experiments show that vaccination with the B.C.G. strain does not protect guinea-pigs or rabbits against infection with fully virulent tubercle bacilli of the bovine type, though it does lengthen the course of the disease. The discrepancy between his results and those of Calmette and Guérin is thought to be due to the difference in virulence of the infecting strain.

#### 149. The Bacteriology of Middle-ear Disease.

E. WIRTH (*Centralbl. f. Bakt.*, June 7th, 1926, p. 501) has examined eighty-four specimens of pus from acute middle-ear disease. The secretion was taken by paracentesis and then examined bacteriologically, particular attention being paid to the *Streptococcus mucosus*. For this purpose the pus, after microscopical examination, was enriched in liver broth and then plated on blood agar. It was noticed that there was often a failure in correspondence between the morphological and the cultural characteristics of *S. mucosus*. The author discusses the meaning of this and comes to the conclusion that the final criterion to employ in the diagnosis of this organism is the formation of the typical slimy colonies on blood agar. Great difficulty occurred in distinguishing it from the pneumococcus; five of the specimens remained sterile on culture, or contained only saprophytic organisms. On account of the difficulty he experienced in the cultivation of *S. mucosus* he is inclined to regard these cases as having been caused by this organism. His final results showed that the *S. haemolyticus* was present in 53.8 per cent. and the *S. mucosus* in 23.8 per cent. of the specimens. These findings agree fairly closely with those of other authors; the discrepancies he regards as being due to the different technique he employed, and to the variations in seasonal incidence manifested by the *S. mucosus*.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### The Incidence of Diabetes.

54. FRANKLIN ADAMS (*Arch. Intern. Med.*, June 15th, 1926, 6) indicates two main forms of the onset of diabetes—acute and the insidious. In cases where the date of onset of disease can be fixed there appears to be a certain seasonal character. The author examined 1,000 case records from the East division of the Mayo Clinic, and found that in 317 the onset was acute, and that such cases were most frequent during spring, autumn, and winter. He notes the close association of the acute respiratory diseases and the onset of diabetes; some patients reported that the disease commenced immediately after a cold in the head, acute tonsillitis, or influenza. This sequence of events may be explained by the patients having been relatively inactive when laid off during the winter months, the existence of an intercurrent pre-diabetic condition, and a respiratory infection predisposed to the onset of diabetes. With reference to the possible inactivity factor it was found that considerably more than half the patients at the Mayo Clinic came from rural districts. The death rate figures for 1922 showed that 6 deaths from diabetes in the Northern States greatly exceeded those from the Southern; if a horizontal line was drawn at 127 degrees latitude, the death rate above it was 13 per 100,000, and below it 8.5. The Northern States have relatively long winter seasons. It was found also that there was gradual increase of incidence up to 60 years of age, and thereafter a sharp decline. Sex incidence was fairly equal—32 per cent. being males and 42 per cent. females. The chief geographical area was the Middle West of the United States, and he adds that to obtain a reliable estimate of racial factors other sections of country should be studied similarly.

#### 51. Routine Examination of Cerebro-spinal Fluid.

Dr. CANTAROW and A. CANTAROW (*Amer. Journ. Med. Sci.*, Dec. 1925, p. 553), as the result of the study of 210 cases, make the following conclusions: (1) The colloidal leucosin adds nothing to the knowledge obtained in the routine examination of the cerebro-spinal fluid. (2) Normal variations of spinal fluid sugar are associated with variations of blood sugar from moderate hypoglycaemia to moderate hyperglycaemia. For this reason the time of day and hours to meals must be considered in examination of the fluid unless simultaneous blood sugar determinations are made. (3) The essential cause of hyperglycorrhachia is increased permeability of the protective barrier of choroidal endothelium and cerebro-spinal capillary endothelium. Conditions causing hyperglycorrhachia are those that have an essentially vascular pathology, especially encephalitis and early forms of syphilis of the central nervous system. (4) Great increase in globulin and high sugar content are characteristic of increased intracranial pressure in general and particularly of brain tumour. High sugar values are also found in various functional mental disorders. (5) The essential cause of hypoglycorrhachia is glycolysis, which occurs to a large extent in acute suppurative meningitis and to a slight degree in tuberculous meningitis. (6) Sugar determinations are of great value in the differential diagnosis of tuberculous meningitis, especially from epidemic encephalitis.

152. Active Immunization against Diphtheria by  
Anatoxin.

**Anatoxin.** I. ROTBINOVITCH, G. LOISEL, and A. LAFFAILLE (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, May 20th, 1926, p. 737) record their observations on the duration of active immunity conferred by immunization with anatoxin of children exposed to diphtheria. Out of twenty-three children with a positive Schick reaction the immunity conferred by a single injection of 0.5 c.c.m. of anatoxin still persisted in seventeen after fifteen to twenty-five months, and in six the immunity was lost during the same period, so that a single injection of 0.5 c.c.m., which is sufficient in some cases, is inadequate in others. In another seventeen cases with a positive Schick reaction the immunity obtained by two injections of anatoxin (0.5 and 1 c.c.m.) was still present in all the cases examined after twelve, nineteen, twenty-three, and twenty-four months. Simultaneous immunization in children whose Schick reaction remained positive after two injections of anatoxin played only a very unimportant part, and in most cases a third injection of anatoxin was necessary to produce immunization.

L. MARTIN, G. LOISEAU, and A. LAFFAILLE (*ibid.*, p. 745), as the result of immunization by anatoxin of a total of 4,950 persons in schools, sanatoriums, and preventoriums in which there had been an outbreak of diphtheria, came to the following conclusions: (1) In order to produce a high percentage of immune subjects three injections of anatoxin should be given, the first dose consisting of 0.5 c.c.m., the second of 1 c.c.m., and the third of 1 or 1.5 c.c.m., with an interval of a fortnight or three weeks between the injections. (2) Cases of diphtheria which developed in the course of immunization always occurred in subjects who had had only one or two injections or whose third injection had been given too soon after the second. (3) Attacks of diphtheria occurring after two injections of anatoxin were very mild and might even clear up spontaneously without antitoxin. (4) The reactions were not appreciably more pronounced in actually tuberculous subjects or in those suspected to have tuberculosis.

153. **Marria's Test in the Diagnosis of Typhoid Fever.**

153. **Morris's Test in the Diagnosis of Typhoid.** P. FORMICOLA (*Il Morgagni*, July 18th, 1926, p. 897) has performed Morris's test on a number of patients suffering from febrile conditions. Atropine was injected, and the number of pulse beats counted in the usual way. In a series of 10 typhoid and 15 paratyphoid patients the reaction was positive ten times. Two positive reactions were obtained in Malta fever patients, three in patients with a dysenteric type of enterocolitis, five in patients with febrile diarrhoea, and four in patients with pulmonary tuberculosis. Altogether twenty-four positive reactions were obtained in an examination of 115 patients. The author concludes that the test is useful as an indicator of increased excitability of the vagus, but as a diagnostic test of typhoid fever it is not sufficiently specific.

### Surgery.

### Torsion of the Gall Bladder.

151. **Torsion of the Gall Bladder.** June 26th, 1926, P. MATHEU (*Bull. et M. m. Soc. Nat. de Chir.*, June 26th, 1926, p. 701) reports a case of torsion of the gall bladder in a woman, aged 55 years, and remarks that this is a somewhat rare condition, the present case being the eighteenth that has been recorded. All these cases showed a special predisposition to this condition in that a long and well marked mesentery was present. The gall bladder often lies free or floating within the abdomen, and in only two of the eighteen cases were gall stones present in it. The condition occurs usually in elderly females with general ptosis. The diagnosis is seldom made before operation, the condition being usually regarded as some variety of acute abdominal disease, such as cholecystitis, appendicitis, perforated gastric ulcer, or intestinal obstruction. There does not appear to be any pathognomonic sign of such torsion; the signs, however, are usually sufficiently acute to call for urgent operation. Cholecystectomy is the operation of choice and has a relatively good prognosis; it was followed by recovery in 67 per cent. of cases. Untwisting of the gall bladder and cholecystotomy has been performed in some of the cases where the gall bladder appeared healthy. In the case recorded the patient made a satisfactory recovery.

### Ureteral Stricture.

155. A. H. PEACOCK and R. F. HAIN (Surg., *Gynecol. and Obstet.*, July, 1926, p. 54) record their observations on 76 cases of ureteral stricture, which they maintain is not an uncommon disease. As regards the etiology, the foremost among the causal factors are infection and trauma, the former playing the far greater part. A history of acute or chronic infection was present in 63 cases—the acute infections in order of frequency being influenza, scarlet fever, diphtheria, pneumonia, puerperal fever, and otitis media; and the chronic, tonsillitis, dental infection, enteritis, prostatitis, cholecystitis, osteitis, sinusitis, and salpingitis. Of the 76 cases of urethritis, 45 occurred in males and 31 in females. The stricture was about equally divided between the two sides, 42 being on the right and 34 on the left. The symptoms were frequently those of ureteral or renal colic, so that the patient was thought to be suffering from renal calculus. The authors maintain that many cases of obscure abdominal pain have been due to ureteral stricture and have been relieved by dilatation, and that a number of abdominal operations have been needlessly performed owing to ureteral stricture which

was the cause of the symptoms not having been diagnosed. Of the authors' series 46 patients were cured after three or four dilatations; in 39 per cent. the results were not known; 8 per cent. were relieved, 4 per cent. were not improved, and two patients died of uraemia.

#### 156. Primary Tuberculosis of Striped Muscles.

C. F. BIANCHETTI (*Il Policlinico*, May 15th, 1926, p. 221) reports two cases of primary tuberculosis in the trapezius and adductor longus muscles respectively. These cases are not common and are called primary because there are no detectable signs of tuberculosis elsewhere, although probably other foci do exist; they are haematogenous and start in the perivascular or connective tissue and not in the muscle fibre itself. In the first case, a girl aged 14, some pus was aspirated from the tumour in the trapezius and on injection into a guinea-pig induced tuberculosis; the mass was subsequently excised. The adductor mass occurred in a man aged 27 and was similarly excised. It seems doubtful whether traumatism plays any part in the formation of these tumours. The diagnosis is usually made by exclusion and the various general methods for detecting tubercle. Pain is not marked, but there is usually some functional disability in the muscle concerned. A few cases have been successfully treated by aspiration and injection of iodine, but the author thinks that as a rule it is better to excise the whole mass, and if necessary an area of muscle as well. About forty similar cases, with confirmatory diagnosis, have been reported by various writers. They may occur as nodules, but more generally as abscesses, and have to be distinguished from gummata, cysts, angiomas, sarcomata, or infective abscess. The prognosis, so long as the condition is purely local and there is no secondary infection, is relatively good.

#### 157. Perforation of Meckel's Diverticulum by a Foreign Body.

S. LINDQVIST (*Zentralbl. f. Chir.*, July 10th, 1926, p. 1756) remarks that the presence of Meckel's diverticulum is seldom recognized until some untoward symptoms occur; he records the following case on account of the difficulty in diagnosis. A man, aged 21, had had numerous attacks of pain in the right iliac fossa and groin during the past year; it was considered that the patient was suffering from recurrent appendicitis. After the last and most severe attack he was admitted to hospital and an immediate appendicectomy was performed. On opening the peritoneum the appendix was seen to be slightly congested and it was removed. There was also engorgement of the vessels of the lower part of the ileum. On exploration of the pelvis a Meckel's diverticulum was found, hidden by a coil of small intestine, while between the coils of intestine there was a considerable collection of sero-purulent fluid. The diverticulum was 10 cm. in length and as thick as a man's index finger. At the free end there was a bladder-like accessory diverticulum as large as a hazelnut. The diverticulum and the adjacent bowel were distinctly congested, discoloured, and covered with fibrinous flakes. The diverticulum had perforated and its lumen contained a splinter of wood 3 cm. in length and 1.5 cm. in breadth. The diverticulum and the adjacent discoloured ileum were resected and an entero-anastomosis was performed. A small rubber drainage tube was inserted in the abdominal incision. Pathological examination showed that this was a genuine diverticulum. The history and clinical symptoms supported the diagnosis of acute appendicitis. Lindqvist adds that if a careful examination had not been made after removal of the appendix the actual pathological condition would have been overlooked and a more serious operation would have been necessary subsequently.

#### 158. Femoral Thrombosis complicating Appendicitis.

G. BOLOGNESI (*Lyon Chir.*, May-June, 1926, p. 290) discusses the association of left femoral thrombosis and acute appendicitis, and records four cases. The principal feature of this condition is that it occurs in young people, usually females. It may follow acute appendicitis even when there is no operation. The history shows in many cases that there is a tuberculous lesion elsewhere in the body. This condition occurs in about 1 per cent. of cases of acute appendicitis, and is met with in many other diseases, including articular rheumatism, gall stones, and after operation for hernia and renal disease. It is suggested that the thrombosis originates in some special predisposition of the patient and is not really the result of the disease. In view of the presence of some tuberculous lesion in these cases this may be the predisposing element, while the infective process in acute conditions may be of importance in the etiology. The occurrence of femoral thrombosis on the left side probably depends on the greater length and obliquity of the left external iliac vein producing a slowing of the circulation on this side.

## Therapeutics.

#### 159. The Treatment of Epidemic Encephalitis.

R.-A. LEX (*Bruxelles Méd.*, May 9th, 1926, p. 833) observes that three drugs seem to be valuable in the treatment of epidemic encephalitis—hexamethylene-tetramine, sodium salicylate, and sodium iodide—though a specific remedy has not yet been found. A daily dose of 10 to 12 grams hexamethylene-tetramine is given intravenously or intramuscularly, combined with oral administration pushed to the limits of gastric tolerance; intraspinal injections of 1 to 2 grams a day are also given. Von Economo now prefers sodium iodide given intravenously in a 50 per cent. solution in doses slowly increasing from 6 to 20 c.c.m. a day. Carn and Blamontier have had brilliant results with sodium salicylate, which must be given intravenously, but in very dilute solution (4 per cent.) to avoid sclerosis of the vein. The dose varies from 1 to 6 or even 8 grams a day according to the severity of the case. The intravenous administration of hexamethylene-tetramine may be combined with it. Intraspinal serotherapy, by means of auto-serum or convalescent serum, has been tried with favourable results in certain cases. Ley asks whether the so-called sequels should properly be regarded as such, or rather as evidence of prolonged encephalitic infection, the latter event justifying a continuation of therapeutic measures specially directed against such infection. Levaditi and Poincloux introduced the intraspinal injection of a vaccine of the specific virus, and Lefevre de Arric has obtained with it improvement in certain states of hypertonus. Claude reports marked improvement in severe Parkinsonism in young patients following on inoculation with recurrent fever. Roch has tried non-specific protein therapy by the intraspinal injection of casein. Bruynoghe has demonstrated the bactericidal action of radium on the virus of encephalitis *in vitro*. At present much treatment remains symptomatic. Conditions of hypertonus are improved after the administration of atropine, tremors after scopolamine or morphine, and myoclonus and choreic symptoms after antipyrine, arsenic, and magnesium sulphate.

#### 160. The Intravenous Administration of Mercurochrome.

H. H. TRONT (*Surg., Gynecol. and Obstet.*, May, 1925, p. 633) after summarizing the research work upon mercurochrome-220, considers its intravenous administration justifiable in cases with a positive blood stream infection in which a possible foci of infection have been dealt with. He states that the justification or otherwise for the continuation of intravenous medication rests upon the answer to the question whether a blood stream infection spreads in the same way as an infection in a solid cellular tissue and whether it is possible to kill micro-organisms with a dye or other substance without at the same time harming living cells. From previously recorded cases of severe blood stream infection treated intravenously with mercurochrome-220 the percentage of recoveries appears to be higher than can be attributed to mere coincidence. Tront reports fourteen cases with satisfactory recoveries in which the drug seemed to be of definite benefit. He mentions the dangers of overlooking some focus of infection which could be surgically treated, of the reaction following administration, and of its indiscriminate use when blood cultures have not been made. He concludes that all intravenous medication has great potential dangers and should only be administered in well equipped hospitals.

#### 161. Antirachitic Value of Irradiated Orange Juice.

H. L. MASLOW, D. H. SHELLING, and B. KRAMER (*Bull. Johns Hopkins Hosp.*, July, 1926, p. 56) report the results of preliminary experiments which indicate that antirachitic properties can be imparted to orange juice by exposure to the rays of a mercury vapour quartz lamp. Rachitic rats fed on orange juice thus irradiated commenced to show healing as soon as five days after commencing the treatment; the process was practically complete at the end of about a fortnight. The inorganic phosphorus in the blood serum was found to be raised. The authors are investigating the antirachitic value of irradiated orange juice in the treatment of children suffering from rickets, and the effect of irradiation on the antiscorbutic properties of various specimens of orange juice which differed in their degree of acidity. They are also studying the length of time during which such irradiated orange juice is able to retain its value in the treatment of rachitic animals. Comparing their results with the work of Howland and Kramer and de Bosanyi, they suggest that there may be two types of healing in rickets. In the first healing spreads from the ends of the epiphyseal cartilage into the metaphysis and is associated usually with a raised serum phosphorus content; in the second the healing begins in the middle of the metaphysis and the serum phosphorus is relatively low.

The aorta was clamped on account of post-partum bleeding, and after expression of the placenta a test 10 cm. long and still covered with serosa was found in the anterior wall of the cervix. Hysterectomy was done successfully. The second patient was a woman, aged 36, who had had two children and numerous artificial abortions. Labour at term was protracted owing to uterine inertia and was accompanied by pyrexia; it was terminated by application of Kielland's forceps to the high-lying transversely placed head. The child, born alive, weighed 3.3 kilograms; the mother died thirty minutes later, apparently from heart failure, of which physical signs had previously been noted. At autopsy an incomplete tear of the cervix and a complete transverse rupture 8 cm. long at the cervico-corporal junction were found. Microscopically the first case showed chronic culometritis, chiefly of the cervix, and infiltration of the degenerated myometrium in the neighbourhood of lymphocytes and leucocytes. In the second case an acute membranous endometritis and an acute sero-parietal myometritis with arteritis and thrombo-phlebitis were present. In neither case was there any evidence of scar formation.

#### 169. Physiology of the Vernix Caseosa.

ACCORDING to H. KIEFFER (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, May, 1926, p. 273), the vernix caseosa is derived chiefly from choesterides and glycerides secreted by the amniotic epithelium; the foetus contributes epidermal cells and (from the sebaceous glands) a small proportion of the fatty substances. The amniotic secretion is deposited, by reason of the foetal movements, on the back and outer surfaces of the limbs; vernix caseosa is always absent from the chest. This substance is not to be regarded as an excretion but rather as a pabulum for nutrition of the embryo; it contains lipoids and glycerides which are anti-haemolytic and antibacterial. It is not advisable to remove the vernix caseosa after birth, as is the common custom; if left it is absorbed in from eight to twelve hours. By leaving the vernix caseosa on the newborn body and by accelerating the attention to and toilet of the baby before it is dressed Keiffer has found that the incidence of icterus neonatorum may be reduced to a negligible minimum, as compared with the much larger figures usually given—according to Porak, 50 to 63 per cent.

#### 170. Puerperal Inversion of the Uterus.

R. DE PORENTA (*Riv. d'Obstet. e Ginecol. Prat.*, July, 1926, p. 321) does not favour application of tampons or colpeurynters as means of treatment of irreducible post-partum inversion of the uterus; he believes that, manual replacement having proved impossible, recourse should be had, as a preliminary to operative correction, to anterior or posterior colpotomy. The latter is technically easier and has the advantage of avoiding approach to the bladder; it should be performed as soon as the state of shock accompanying the inversion has sufficiently subsided. In certain cases hysterectomy may be indicated by signs of sepsis or incipient gangrene of the uterus. De Porenta records a case of acute post-partum inversion of the uterus in a woman aged 21, who came first under medical observation forty-three hours after a delivery in which traction had been exercised on the cord during the first stage. Pyrexia was present and the inversion was complete and irreducible by manual manipulation under general anaesthesia. A rise of temperature and pulse rate followed on two occasions the introduction into the vagina of a Braun's colpeurynter, and also a further attempt at manual reduction. The fever disappeared, the general condition improved with rest and douches of alcohol, and finally Küstner's operation was performed on the twelfth day. A year later bimanual examination gave normal findings save for retroversion of the uterus.

## Pathology.

#### 171. The Production of Immune Bodies.

E. BENASSI (*Arch. di Patolog. e Clin. Med.*, May, 1926, p. 145) has investigated the effect of poisoning the haematopoietic and blocking the reticulo-endothelial systems of rabbits on the production of agglutinins to *B. typhosus*. Pure benzol was injected into a series of animals, the doses being so graded that after about ten days the circulating leucocytes had fallen to 2,000 per c.mm.; further injections were given to maintain them at this level. Injections of carmine or of lithiocarmine were then made with the object of blocking the cells of the reticulo-endothelial system and, shortly after, heat-killed typhoid bacilli were given intravenously, the dose being in strict proportion to the weight of the animal. At fixed times subsequently the agglutinin titre of the blood was determined as accurately as possible. The injections of

carmine and of typhoid bacilli were repeated on one or two occasions, and the titres reached by the different animals again compared. In another series a preliminary splenectomy was performed, and the blocking of the cells carried out by trypan blue or saccharated ferric oxide. The results obtained from these experiments were as follows. Blocking of the reticulo-endothelial system by itself tended to favour the appearance of agglutinins; benzol poisoning by itself had the reverse effect. When the two were combined the agglutinin production was much the same as in control animals receiving typhoid bacilli only. Neither splenectomy plus blocking nor splenectomy combined with blocking and benzol intoxication had any noticeable influence on the production of agglutinins. The differences observed after the various procedures were always most noticeable a few days subsequent to the start of the experiment; later on they tended to disappear, so that the titres of all the rabbits approached each other closely. From this the author concludes that in all probability the production of antibodies is a function not of one particular kind of cell but of several different kinds scattered throughout the whole body. When one set is put out of action the others are therefore able to compensate for their loss.

#### 172. The Blood in Eclampsia.

H. T. STANDER and A. H. RADELET (*Bull. Johns Hopkins Hosp.*, June, 1926, p. 423) have examined the blood of patients suffering from eclampsia, and find that there is a high mic acid value; that lactic acid is increased markedly, which is only partially due to muscular activity; and that there is a decrease in the power of combining with carbon dioxide. They claim to have shown also that there is a definite tendency towards a hyperglycaemia which is often associated with a high figure for inorganic phosphorus. As a rule there was little or no increase in non-protein nitrogen (blood), and when such an increase was found it was due to nephritis or was associated with advanced stages of the disease. The authors do not feel able to express an opinion about the extent to which these alterations in the blood chemistry may be due to the hepatic lesions which are usually recognizable in eclampsia.

#### 173. The Blood Serum in Pernicious Anaemia.

ACCORDING to A. M. FISHBERG (*Am. Journ. Med. Sci.*, July, 1926, p. 81), the characteristic skin colour of pernicious anaemia is chiefly due to the yellowish discoloration of the blood serum. The increase in the serum pigmentation is a very constant feature, Naegeli having observed it in every one of twenty cases, and Fishberg finding it in his seventeen cases. The colour of the serum is golden or golden brown, and not the usual straw tint. During the active periods of the disease the serum is more highly coloured than normally. The deeper pigmentation has been shown by van den Bergh to be due to an increase in the bilirubin content, and the presence of haematin has been demonstrated by Schumm in the serums of patients with pernicious anaemia. Fishberg believes that in any case of anaemia the presence of a pale blood serum definitely contraindicates the diagnosis of pernicious anaemia, and is therefore of special value in the differential diagnosis between the secondary anaemias of malignant disease and a primary anaemia of the pernicious type.

#### 174. The Sedimentation Test in Infantile Syphilis.

SINCE the Wassermann test in sucklings is unreliable C. GIAUME (*La Pediatria*, June 1st, 1925, p. 593) has tried to discover whether a marked increase in the speed of sedimentation of the red blood cells (Georgi's reaction) has any real diagnostic value, and whether various antisyphilitic treatments have any influence in controlling this speed. Thirty-nine cases of hereditary syphilis were divided into three groups, which were treated respectively with mercury (inunctions or vapour bath), arsenobenzol, and bismuth preparations; there was a fourth group of healthy controls. Giaume found that in healthy sucklings the sedimentation rate showed wide variations according to the individual, but it was more rapid in the congenital syphilitic babies as a rule. This was not diagnostic, since the rate was also accelerated in other morbid conditions. However, during the first two weeks of life, in the absence of tubercle or common infections, a marked and constant acceleration was strongly suggestive of syphilis. The author concludes that the reaction is positive in about 65 per cent. of cases, but a normal reaction does not contraindicate syphilis. In many cases the sedimentation rate corresponded with the severity of the symptoms. Treatment in 80 per cent. of the cases caused a slowing down of the rate parallel with the disappearance of clinical signs; this slowing was greatest after treatment with arsenobenzol. Giaume concludes that a marked and constant acceleration has in practice a relative diagnostic value, but only in infants.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 175. Arterial Embolism following Intramuscular Injection of Bismuth Carbonate.

R. BARTHÉLEMY (*Bull. Soc. Française de Derm. et de Syph.*, May, 1926, p. 372) describes a case of arterial embolism after the intramuscular injection of bismuth carbonate, which, recognized recently as superior to the oxide on account of its more rapid absorption, is nevertheless an insoluble salt and may give rise to embolism. The early symptoms of embolism are often mistaken for interstitial haemorrhage or nerve injury. Barthélemy's patient had palmar syphilides resembling psoriasis and a positive Wassermann reaction. Weekly injections of bismuth carbonate 0.2 gram in 2 c.cm. vegetable oil were employed. The tenth injection was given in the left buttock; no bleeding followed the withdrawal of the platinum needle, but the patient remarked that he felt the injection a little more than the previous one. He had no sleep on account of pain, and next morning the whole buttock was swollen, tense, and painful. The skin around the puncture was of a livid violet colour, hard, and very painful on pressure; it was surrounded by an itching urticarial ring. Small bullae formed on the central area but no actual sloughing occurred. The condition gradually improved, and ultimately cleared up in three weeks, with the exception of a small indurated area.

### 176. The Brain in General Paralysis after Malarialtherapy.

G. P. FRETZ (*Nederl. Tijdschr. v. Geneesk.*, May 15th, 1926, p. 1938), who records his own observations, states that thirty-six brains of patients who had died of general paralysis after treatment by malaria were examined by Sträussler and Koskinas at Vienna, which is the centre for the malarial treatment of general paralysis. In three cases of death occurring during a remission they found hardly any anatomical changes. In nine cases the changes were slight although no clinical remission had occurred. These investigators are of opinion that half the cases which have had more than five febrile attacks were favourably affected in an anatomical respect, and that the anatomical remission after the malarial attacks. In two cases died during treatment Sträussler and marked infiltration which they regarded as an expression of a recrudescence of the infective process preceding recovery. Frets, from examination of the brains of ten paralytics who had been treated by malaria, found that the microscopical appearances as a general rule confirmed the clinical and serological findings. Improvement did not occur in every case, and a case showing clinical improvement did not always show a corresponding serological improvement. Microscopical examination showed that inflammatory phenomena such as the occurrence of lymphocytes and plasma cells are less in the brains of treated than of untreated cases, though this rule is not invariable. Cases may occur in which there is a diminution of inflammatory phenomena in the absence of any clinical improvement. Whether the reverse occurs—that is, clinical improvement without any diminution of inflammatory phenomena—is unknown.

### 177. Complications of Artificial Pneumothorax.

C. LAMAILLON (*Journ. de méd. de Bordeaux et du Sud-Ouest*, May 25th, 1926, p. 413) records two unusual complications of artificial pneumothorax in males aged 42 and 17 respectively. The first patient, who had received numerous previous insufflations, suddenly developed transient hemiplegia due to gas embolism after 2 or 3 c.cm. of gas had been injected. In the second case sudden death occurred at the fifth insufflation after injection of about 20 c.cm. of gas. Accidents of this kind are most likely to occur when the exploration of the thorax has been difficult and must be repeated owing to partially adherent pleura. The author states that nothing need be feared when no adhesions are present, but when it is impossible to be sure of finding a completely free pleura it is best not to employ artificial pneumothorax.

### 178. The Inheritance of Epilepsy.

W. R. BRAIN (*Quart. Journ. Med.*, April, 1926, p. 299) investigated the subject of the inheritance of idiopathic epilepsy by reviewing the literature and making an inquiry into the family history of over 200 epileptics. Of these, 56 (28 per cent.) had a family history of epilepsy—a percentage in substantial agreement with the findings of other observers. A family

history was obtained more frequently in the case of females than of males, and it was found that the onset occurred in the first decade of life in a larger proportion of those with a family history of epilepsy than of those without such a history. Early convulsions (28 per cent. of 176 epileptics) occurred almost twice as frequently in those giving a family history of the disease as in those giving none. It was found that epileptics transmitted the disease to about one in twenty of their offspring, but this proportion cannot be accepted finally in view of the small numbers under investigation. Nearly half of the epileptic patients had been the first- or second-born members in their families. It is suggested that the greater liability of first-born children to head injury during birth may be the cause of this greater incidence of epilepsy. The incidence of insanity among the relatives of epileptics was found to be no higher than in the general population. Brain considers that the investigation points to there being a predisposition, which in at least 28 per cent. of the cases is inherited, as an etiological factor, but that our present knowledge is insufficient to justify the application of Mendelian principles to the treatment of epilepsy.

### 179. A Fever in Queensland resembling Mild Typhus.

F. T. WHEATLAND (*Med. Journ. of Australia*, March 6th, 1926, p. 261) states that although cases of typhus have occurred on ships arriving in Australia, and occasionally in the earlier years among the resident population, no epidemic of the disease has been recorded in Australia since 1860. In 1922 and 1923 Hone reported a series of cases in Adelaide resembling Brill's disease or the mild form of typhus occurring in New York, but with no evidence of infestation by lice. Between June and September, 1925, Wheatland observed thirty-eight cases at Toowoomba, Queensland, of a disease probably identical with that observed by Hone, characterized by a fever of about twelve or fourteen days' duration with severe headache and a macular rash on the body and limbs. The Widal reaction was negative, and the Weil-Felix reaction was positive in dilutions ranging from 1 in 80 to 1 in 10,240. There was a slight leucocytosis of 10,000 to 13,000. Blood cultures during the febrile stage were always sterile. The points against the disease being true typhus were the absence of lice, a negative diazo-reaction, and the insusceptibility of guinea-pigs.

## Surgery.

### 180. Enlargement of the Prostate.

M. ARESU (*Arch. Ital. di Chir.*, March, 1926, p. 301) records his pathological observations on 80 cases of enlarged prostate, consisting of 26 due to concretions, 37 of nodular hyperplasia of the principal prostatic system, 16 of nodular hyperplasia of the principal prostatic system and of the accessory as well, and 1 case of perirethral fibro-adenomatosis. His conclusions are as follows: (1) Normal senile involution of the prostate in the form of diminution in size and number of the tubules and a variable degree of atrophy of the smooth muscle fibres is not often observed. (2) All the prostates of elderly persons found to be enlarged without being adenomatous should be regarded as pathological. Histological examination in all these cases shows an increased deposit of concretions in the excretory and secretory ducts, and the anatomical basis of the enlargement is as follows: a varying degree of dilatation of the glandular cavity, a high degree of hypertrophy and hyperplasia of the smooth muscular tissue, a growth of interstitial connective tissue, and considerable thickening of the fibromuscular capsule of the gland. This is the type of prostate most frequently seen in old men. (3) Cases in which the principal prostatic system is affected are the most numerous, the areas of predilection for the hyperplasia being in the first place the lateral lobes and then the prespermatic commissure. Involvement of the anterior lobe and retrospermatic commissure is rare. The new growth corresponds to the type described as adenomyofibroma, in which the adenomatous element predominates. (4) The next most frequent cases are those in which both the principal and accessory systems are affected together. In these the proliferation due to the principal system is characterized by a preponderance of adenoma over fibroma and myoma, while that due to the accessory system is distinguished by an excess of fibroma over adenoma. (5) Nodular hypertrophy of the accessory or periurethral system, which is not present

in all individuals, and in some is scanty or entirely absent, is the form least frequently encountered, and in the author's cases was chiefly characterized by predominance of fibroma over adenoma.

#### 181. Periarterial Sympathectomy.

P. STRADIN (*Deut. Zeit. f. Chir.*, Hefte 5 u. 6, January, 1926, p. 338) records his experience of 30 cases at the surgical clinic at Riga University and comes to the following conclusions: (1) The method of periarterial sympathectomy of Jaboulay and Leriche is one of great value, and deserves to be more extensively employed. (2) The most favourable results are obtained in trophic and vasomotor disturbances following nerve wounds (causalgia), in various vaso-neuroses, trophic ulcers of unexplained nature, arterio-sclerotic and post-typoid intermittent claudication, and in a few cases of spontaneous gangrene in the initial stage. (3) The mechanism of the favourable action of periarterial sympathectomy is still mysterious, existing theories contradicting one another. (4) The method should take a prominent place among the palliative operations for spontaneous gangrene. (5) If the proper technique is employed the operation is without risk. In none of Stradin's cases did secondary thrombosis occur. (6) In spontaneous gangrene and intermittent claudication the best results are obtained if sympathectomy is combined with ligation of the veins, and physical treatment is employed before and after the operation. (7) In a normal individual the vasomotor disturbances following periarterial sympathectomy lasted about a fortnight, and differences in the capillaroscopic appearances could be seen after a month. (8) Periarterial injection of spirit can take the place of stripping the artery. In some cases it can be performed more easily and quickly, and does less harm to the arterial wall. Further clinical trials of this method, however, are needed.

#### 182. Nephrectomy for Renal Tuberculosis.

C. A. PERRET (*Journ. d'Urol.*, May, 1926, p. 397) records his opinions, based on a hundred consecutive cases of nephrectomy without a single operative death; 87 of these operations were for renal tuberculosis. The kidney was always reached by the lumbar route and by the retroperitoneal method. The tuberculous cases were frequently associated with pulmonary or joint lesions. When there was a tuberculous focus in the lungs the anaesthetic used was a mixture of ether and chloroform: all the other patients had pure ether. He finds the oblique lumbar incision has definite disadvantages when the kidney is fixed by adhesions. He therefore advises a transverse incision commencing at the border of the lumbar muscles and passing forwards, below the twelfth rib as far as may be found necessary. This incision is rapidly made and gives the best access in difficult cases. After opening the renal fossa the kidney is carefully forced by the fingers. Perret states that the more common complications following this operation are tuberculous meningitis, reflex auria, or embolus and infection from rupture of the kidney. These accidents owe their origin to this stage when the kidney is freed, and can largely be avoided by careful handling. The bladder is irrigated immediately after the operation, since during the handling of the kidney pus may be expressed into the bladder. This is continued daily when there is any vesical infection. The lumbar wound is closed in layers and a glass drain is placed in the depths of the wound for a few days. The operative results have been uniformly satisfactory.

#### 183. Tuberculosis of Mesenteric Glands.

J. R. HEAD (*Annals of Surgery*, May, 1926, p. 622) points out that infection of the mesenteric glands is usually by ingestion and the route is through the intestinal mucous membrane to the glands which drain it. The bacilli are usually of the bovine type. Many of the symptoms and complications are due to periaidenitis and adhesions, while rupture of a purulent or caseous gland may lead to generalized tuberculous peritonitis. The symptoms are often misleading and the picture may be one of chronic abdominal pain with or without acute exacerbations. Pain is usually intermittent and is as a rule referred to the right iliac fossa; rarely it is on the left side. There is frequently an abdominal tumour and the stools may be copious and foul. The chief serious complications are ileitis, abscess formation, perforation, and military tuberculosis. The diagnosis is difficult and is often not made prior to operation; the condition often simulates appendicitis. The treatment is medical and surgical. The operative procedure is determined by the stage of the process. Extirpation of the glands is advised where possible, and resection of the bowel where injury to the vessels is unavoidable; the opening and curetting of caseo-calcareous masses and the drainage of abscesses are necessary. In 78 collected cases there were 8 post-operative deaths. Simple laparotomy, as in tuberculous peritonitis, appears of no benefit in these cases.

405 B

## Therapeutics.

#### 184. Protein Therapy in Peptic Ulcer.

A. DE ZULUETA (*Rev. Clin. de Bilbao*, June, 1926, p. 293), who records his observations on eight cases, states that protein therapy for peptic ulcer was first introduced by Pribam, who out of 77 cases so treated reported that 42 became completely free of symptoms after having suffered intense pain for years. The substances employed were vegetable novoprotein, vaccinemin, caseosan, and boiled milk. In Zulueta's cases casein only was used. Intravenous injections were given twice a week or every other day in doses of 1/2 cg. for the first two occasions, and 1 cg. for the rest. Twelve injections in all were given. Unlike Pribam, who kept his patients on ordinary diet, Zulueta confined them to a strict regimen consisting of milk, eggs, and white fish. The most striking result of the treatment was the rapid disappearance of pain. In two cases there was a marked diminution of the gastric acidity without any other obvious change.

185. V. GRÖMER (*Med. Klin.*, June 25th, 1926, p. 991) quotes the literature dealing with the treatment of gastric ulcer by protein injections, and describes 51 cases of his own. He compares the reaction on the ulcer with that which occurs when protein is given in joint affections—a chronic inflammation is converted into an acute one, with a correspondingly greater tendency to natural cure. He claims that the patient is freed from pain in a relatively short time, and that the x-rays show a diminution or disappearance of the ulcer. The results are, however, not always permanent. His method is to inject novoprotein in doses rising to 2 c.cm. Intramuscular injection has more rapid results than subcutaneous, but he considers intravenous to be the best of all. Ambulant treatment is quite possible. Out of his 51 cases the pain disappeared in 29, was lessened in 18, and in 4 there was no improvement. X-ray examination of 37 patients showed disappearance of the lesion in 18 cases, reduction of the lesion in 11, and no change in 8.

#### 186. Treatment of Pernicious Anaemia.

H. J. BING (*Ugeskrift f. Læger*, May 20th, 1926, p. 475) investigated in the summer of 1925 the fate of the fourteen patients who had been treated in his hospital during the two preceding years for pernicious anaemia. A great variety of treatments had been attempted, and while such standard drugs as iron and arsenic had proved disappointing, protein shock (intramuscular injections of milk) and large doses of hydrochloric acid, given through a stomach tube, had yielded fairly satisfactory results, but in only four out of the fourteen cases could recovery be claimed. The results of injections of milk were apt to be as temporary as they were immediately striking, and they would seem to depend on a passing stimulation of the bone marrow. In the case of a woman aged 40 the percentage of haemoglobin was 37, and the erythrocytes numbered only 1,480,000 per c.mm. She was given an injection of 5 grams of milk every other day, the total number of injections being ten, and recovered rapidly, the haemoglobin rising to 80 per cent. and the erythrocytes to 3 million per c.mm. She was discharged from hospital after a month, feeling quite well. In a man aged 70 the disease had advanced so far, and he had suffered so much from debility, that protein shock treatment was attempted only after some hesitation. But he tolerated the reaction well, and made a remarkable, though temporary, recovery, dying six months later. More permanent would seem to be the beneficial effects of giving once or twice a day (usually in the morning on an empty stomach) from 5 to 8 c.cm. of dilute hydrochloric acid in 200 c.cm. of water, introduced through a stomach tube. Bing records in detail several cases to illustrate the good effects of this treatment.

#### 187. Autogenous Blood Injection in Acute Articular Rheumatism.

A. SORTER (*Med. Klin.*, May 7th, 1926, p. 725) discusses the modern theories of rheumatic infections and observes that the ordinary treatment with salicylates does not always prevent the occurrence of endocarditis. He states that there are three methods of giving autogenous blood injections in this disease: intramuscular injection of 20 to 40 c.cm. of the patient's blood drawn from the cephalic vein; intravenous injection of fresh defibrinated blood, the blood being withdrawn and defibrinated with the strictest asepsis since otherwise there is danger of the occurrence of severe symptoms of shock, palpitation, vertigo, headache, and tinnitus; and intravenous injection of old defibrinated blood. The author finds the intramuscular injection of fresh untreated blood preferable to the other methods. He suggests that the

therapeutic action of autogenous blood injection may depend on a combination of specific immunization processes with a non-specific stimulation therapy. He describes three cases treated during the last year with very satisfactory results. In some cases as much as 40 c.cm. of blood was injected every third day. In others this initial dose was followed by subsequent doses of 20 to 30 c.cm. The author believes that this treatment has had good results when endocarditis or pericarditis was present; it was less efficacious in chronic articular rheumatism.

#### 188. Specific Pollens in Hay Fever.

D. NICHOLSON (*Canadian Med. Assoc. Journ.*, June, 1926, p. 683) considers that the number of varieties of pollen used in testing the susceptibility of patients to hay fever should be as great as possible; he has observed also that the pollen reactions may vary when different varieties of the same plant family are used. It is therefore necessary to have some knowledge of the botany of these plants and of the time of their pollination. When a person is sensitive to a certain plant its blossom rubbed into a scratch will produce a reaction—a valuable point in the diagnosis of those patients who do not come for treatment until the flowering season has begun. Desensitizing treatment should begin before the flowering season of the plant concerned and small doses of the pollen gradually increased and given for a considerable period of time are the best; Nicholson thinks that the treatment should be continued through the whole season during which the particular pollen is prevalent. No definite opinion can be given as to the number of pre-seasonal courses of treatment necessary before permanent immunity is conferred upon the patient; it is rare for one course to be the only one required, and frequently the treatment must be repeated annually, for though it prevents an attack of hay fever in that particular year it lessens the cutaneous reaction of the patients to only a very small extent.

## Ophthalmology.

#### 189. Familial Melanosis Bulbi.

L. M. SELTER (*Monatsschr. f. Kinderheilk.*, March, 1926, p. 587) describes four cases of melanosis bulbi in one family—the father aged 39, his daughter aged 9, and twins, a boy and a girl aged 3 years, being affected. In each case the pigmentation involved both eyes and was situated round the cornea in the form of bluish-grey spots. Examination of the pigmentation by the slit-lamp showed that it was localized on the surface of the sclerotics. The fundus in each case resembled that of a negro, but there was no question of an admixture with any extra-European race, and the visual capacity was good. Apart from a mongolian spot in the lumbar region of the male twin no other anomalies were present.

#### 190. Aniridia in Four Generations.

J. B. LEWIS (*Med. Journ. of Australia*, May 1st, 1926, p. 489) reports a case of double aniridia in a boy, aged 6, accompanied by horizontal nystagmus. His mother had also double aniridia and vertical nystagmus in both eyes. The mother's sister, brother, father, and grandfather were also affected. The mother had diffuse lens opacities, and the sister had had each lens removed for cataract. This is in accordance with what is usually found in aniridia, in which the lens undergoes a change at an early date. Of the boy's two brothers one had normal eyes and the other coloboma of the iris. According to Parsons the influence of heredity is more marked in aniridia than in any other ocular malformation. Guthrie found 10 cases in four generations, Galezowski 31 cases in three generations, de Beck 7 cases of aniridia and 2 of coloboma in three generations, and Mohn found a mother with complete aniridia and two sons with partial aniridia.

#### 191. A Family of Squinters.

F. H. RODIN (*Journ. Amer. Med. Assoc.*, May 22nd, 1926, p. 1613) gives an account of four cases of strabismus in one family. The mother, who had always had right divergent strabismus, had had fourteen children, nine of whom were living. Her husband and eldest six living children had straight eyes, while the youngest three squinted. There was no history of squinting on either the maternal or paternal side of the family. The eldest boy, aged 12 years, and the second child, a girl aged 9 years, had had right internal strabismus since 2 years of age, and the youngest child, a girl aged 6 years, had had left internal strabismus since 1 year of age. The fundi were normal in each case. Lenses did not improve the vision or straighten out the eyes in any one of the squinters.

#### 192. Iridectomy with Winged Incision in Glaucoma.

J. GREEN (*Amer. Journ. Ophthalmol.*, May, 1926, p. 342) describes the variety of iridectomy which he has found most successful; it is a modification of Luedde's operation. A conjunctival flap is dissected down after the manner of Elliot. One suture is passed through the temporal portion of the flap and another through the nasal portion, and the flap is turned down over the corner. A small keratome incision is made and a few drops of aqueous humour allowed to escape. With scissors a 3 mm. snip is made in the sclera at either end of the wound, pointing slightly upwards. A fair-sized iridectomy is now performed with two snips. The sutures are then tied.

## Obstetrics and Gynaecology.

#### 193. The Frequency of Genital Tuberculosis in Women.

C. SCHMITT (*Bull. Soc. de Thér.*, May 12th, 1926, p. 131) states that until recently little attention has been paid to the frequency of genital tuberculosis in women, doubtless owing to the difficulty of early diagnosis and lack of appropriate treatment. Spencer Wells in 1863 performed the first laparotomy for tuberculous peritonitis, which he had mistaken for an ovarian cyst, and in 1890 Osler attributed most cases of peritonitis in young women to an overlooked salpingo-oophoritis of tuberculous origin. The same opinion was expressed by Bonilly three years later. In 1910 Poucet and Leriche drew attention to inflammatory tuberculosis of the uterus and adnexa, and more recently J. L. Faure has maintained that tuberculosis of the adnexa is not rare. Textbooks, however, state that the localization of primary tuberculosis in this region occurs in only 1 to 1.5 per cent. Schmitt thinks that this is undoubtedly an underestimate, the error being due to the statistics being based only on cases which came to operation or necropsy. Tuberculosis when it originates in the genital region is not obtrusive and only rarely gives rise to an appreciable swelling. Consequently tuberculosis of the female genitals is rarely met with by the surgeon, and mainly as the result of an error in diagnosis, as there is no pathognomonic sign attached to it. In cases which come to autopsy the lesions of the uterus and adnexa are insignificant compared with the importance and extent of the lesions of the organs which have caused death. Of sixty-five gynaecological cases sent to Schmitt for radiotherapy, seven, or 10.76 per cent., showed genital tuberculosis which was primary in four and in three was accompanied by other lesions. Good results were obtained by employment of ultra-violet rays.

#### 194. Ovarian Insufficiency.

SIREDEY and Mlle G. LABEAUME (*Journ. de Méd. et de Chir. Prat.*, May 10th, 1926, p. 286) remark that interstitial cells analogous to those of the testis are absent from the ovaries of the human female and cannot be held to be the source of the ovarian internal secretion; the present-day tendency is to regard the liquor folliculi, the corpus luteum, or both, as containing the hormone, and therefore preparations from a part of the organ are not suitable for opotherapy. Cases of ovarian insufficiency are very frequently associated with similar conditions of the thyroid and pituitary glands, and also with alterations in activity of the former, so that combined gland therapy must be controlled by careful clinical observation. At the menopause symptoms pointing to ovarian insufficiency are a tendency to obesity, flushes, and variability of the pulse frequency; many other nervous and toxæmic morbid conditions common to both sexes between the ages of 40 and 50 are apt to be ascribed incorrectly to ovarian dysfunction. Many cases of ovarian deficiency at the menopause respond to treatment directed to the intestinal and the renal functions, hydrotherapy, fresh air, and regulated exercise. In others 20 mg. of thyroid extract, 2 cg. of pituitary extract, and 5 to 10 cg. of ovarian substance may be given in cachets or tablets three or four times a week for two to three weeks, separated by weekly or fortnightly intervals. Opotherapy is contraindicated in the artificial menopause following x-ray or radium treatment; Bécère and others, as well as the present authors, have seen congestive crises, metrorrhagia, and undesirable nervous phenomena occur when this precept has been ignored. Primary ovarian insufficiency is most usually detected in a girl of 13½ to 15 years of age who has not menstruated, is of robust appearance, with fine skin and well developed breasts; the pubic and axillary hair is deficient, the hands are red in warm and violet in cold weather, and the feet are cold. Such patients are readily fatigued and lethargic, and suffer from headaches. A similar condition sometimes arises a few years after establishment of menstruation; the menses become scantier and irregular, and the

weight increases owing to the deposit of fat almost exclusively on the abdomen and the upper part of the thighs. A combined ovarian-suprarenal syndrome is present, with frequently in addition a thyroid hypoactivity as indicated by dryness of the skin, ichthyosis, urticaria, asthma, headaches, or poor development of the external portion of the eyebrows—or some combination of these conditions. Tuberculosis and syphilis play an important etiological part in some of these cases. The proportions of the extracts of the ductless glands which are given should be regulated carefully according to the clinical picture; the dosage, especially of thyroid extract, needs careful watching. A beginning may be made with moderate doses such as 1 cg. of thyroid extract, 1 to 2 cg. of pituitary extract, 10 cg. of suprarenal, and 10 to 20 cg. of ovarian substance, four times weekly with the midday meal, for three weeks in the month; general treatment must always be associated. Ovarian insufficiency in combination with that of other endocrine glands is sometimes manifested in previously healthy subjects between the ages of 25 and 35 years by periods of several months' amenorrhoea; such cases are usually consecutive to abnormally prolonged lactation.

#### 195. Signs of Congenital Syphilis in the Newborn.

COMMANDEUR and RHENTER (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, May, 1926, p. 317) state that of 406 infants recognized as congenitally syphilitic among 49,000 born at two obstetrical clinics, only 127, or 31.2 per cent., showed clear clinical signs of syphilis. Palmo-plantar pemphigus, excessive size of the abdomen with or without hepatic enlargement or ascites, and splenic enlargement were the most frequent signs, while ano-genital circinate ulcers, icterus, and buccal mucous plaques were among the most uncommon. In about three-fourths of the cases of congenitally syphilitic infants the placenta weighed more than one-fifth of the foetus, and in about one-half it weighed at least one-quarter as much. Disproportionate weight of the placenta was regarded as a sign of congenital syphilis if the mother was manifestly syphilitic or if the foetus was macerated. In about one-fourth of the cases a diagnosis of congenital syphilis was based solely on findings at necropsy in macerated or other stillborn foetuses or in those dying shortly after birth; hepatic enlargement, splenic enlargement, and lesions of the diaphyseal cartilage (Wegner's sign) were present in 78, 81, and 65 per cent. respectively.

## Pathology.

#### 196. The Relation between Social Status and Cancer Mortality.

M. YOUNG (*Journ. of Hygiene*, July, 1926, p. 203) has analysed the recorded deaths at different ages from cancer in different parts of the body in groups of men following different occupations in England and Wales during the three-year period 1910-12. The social classes considered were the first five in the Registrar-General's classification, ranging from the upper and middle classes to the unskilled workmen. It was found that the mortality from cancer in the lower classes was higher than that in the upper. Thus the standardized death rate from cancer in the several parts of the body investigated (these comprised 92 per cent. of the total mortality) for males of 25 years of age and upwards was 1,982 per million among the unskilled workmen and 1,525 per million among the upper and middle classes. In most parts of the body, including the tongue, oesophagus, and stomach, the mortality rates from cancer were higher in men of the lowest social status. Mortality from cancer in other parts of the body—namely, the bowel, prostate, and probably the pancreas—was higher in men of the best social status. The author discusses the possible explanations of these results, and points out that whatever hypothesis is suggested—auto-intoxication, high living, overfeeding—it must take into account the varying distribution of cancer in the alimentary tract; it must explain also why cancer of the stomach is commoner in men of the lower classes, and cancer of the bowel is commoner in men of the higher classes.

#### 197. Regulation of the Number of Blood Platelets.

H. KOSTER (*Journ. Exper. Med.*, July, 1926, p. 75) has carried out some experiments on the factors influencing the number of blood platelets. Bedson showed that removal of the spleen in an animal was followed by a rise in the circulating platelets; after about a month, however, the number had returned to normal. This suggested that the spleen was concerned in the normal destruction of platelets; its removal was therefore followed by a rise in these bodies. The gradual return to normal indicated that a hyperactivity of physiologically related tissue compensated for the loss occasioned by splenec-

tomy. The author has studied this problem, not by excising the spleen, but by blocking the whole of the reticulo-endothelial system. Guinea-pigs were chosen, and daily counts were made of their blood platelets. The variation was not great over the period studied; the average count for all the animals was 304,416 per c.mm. The animals were then injected subcutaneously with 5 c.cm. of a 0.5 per cent. solution of trypan blue in freshly distilled water, and the injections were repeated four days later. Daily counts of the platelets revealed an extraordinary rise, commencing on the fifth day after the first injection, and continuing rapidly till the maximum on the ninth day; the average for all the animals was then 1,280,000 per c.mm. A sharp fall occurred during the next three days, followed by a less steep decline. About three weeks after the commencement the count had nearly reached normal. From these experiments it appears that blockade of the reticulo-endothelial system results in a marked increase in the number of circulating blood platelets. The increase, however, is transitory and is soon followed by a return to normal; this occurs even though the blockade is maintained by repeated injections. The author concludes that the mechanism of platelet destruction is complicated, and that phagocytosis by cells of the reticulo-endothelial system is only one method by which this is accomplished.

#### 198. Tubercle Bacilli in the Faeces of Children.

G.-J. GONÇALVES COSTA (*C. R. Soc. de Biologie*, July 2nd, 1926, p. 330) has examined the faeces of 22 children, varying from 1½ to 12 years of age, for the presence of the tubercle bacillus. About 20 grams of faeces were suspended in a 25 per cent. solution of sodium chloride, and the mixture was filtered through sterile gauze. The filtrate was transferred to two centrifuge tubes, and mixed with an equal quantity of antiformin. After thorough shaking half the amount of an ether-ligroin mixture was added; the tubes were again shaken till the ether was evenly distributed throughout, and were then centrifuged at 3,000 to 4,000 revolutions a minute for twenty minutes. The bacilli collected beneath the layer of ether were removed and stained by Ziehl's solution, using acid alcohol for decolorization. The 22 children examined were clinically and radiologically suffering from pulmonary tuberculosis; they all gave a positive tuberculin reaction. Sputum was obtained from 14 of them, and in 8 instances was found to contain the tubercle bacillus. From an examination of the faeces acid-fast bacilli were found in 14 cases; the remaining 8 were negative. Thus by the faecal method 6 more positives were registered than by the sputum method, and in no case was the tubercle bacillus found in the sputum alone. To ascertain whether the bacilli in the faeces were really tubercle bacilli the author injected four positive specimens into guinea-pigs; the animals developed tuberculosis in each case. He concludes that the bacteriological diagnosis of pulmonary tuberculosis in children should always include an examination of the faeces.

#### 199. Glucose and the Production of Agglutinins.

N. PARISE (*Il Morgagni*, May 23rd, 1926, p. 641) recalls the work of Iacono in 1923, who found that the serum of perfectly normal persons would agglutinate such organisms as *B. typhosus*, *B. paratyphosus* A and B, *B. melitensis*, *B. dysenteriae*, and *B. tuberculosis*, provided that those were suspended in a 4.7 per cent. solution of glucose. This agglutination, which is undoubtedly non-specific, is probably due either to an alteration in the hydrogen-ion concentration or to a change in the surface tension. To ascertain whether glucose is able to influence the agglutinating power of the serum in a living animal the author made a number of experiments on rabbits. A small quantity of serum was collected from four animals and tested against *B. typhosus*, *B. paratyphosus* A and B, and two other members of the paratyphoid group. In no instance were agglutinins present within the range of dilutions employed. Each of the four rabbits was then injected intraperitoneally with 10 c.cm. of a 4.7 per cent. solution of glucose. The injections were repeated three times at intervals of four days, and at a similar interval after the last injection the animals were bled and their serum tested against the same organisms as before. All four rabbits agglutinated *B. typhosus* to between 1 in 300 and 1 in 500; *B. paratyphosus* A to between 1 in 80 and 1 in 200; and *B. paratyphosus* B to between 1 in 80 and 1 in 150. Three further animals were selected as controls; two of them received similar quantities of saline in place of glucose, and one was not injected at all. None of these animals reacted in any way with the organisms mentioned. It would appear, then, that not only does the suspension of organisms in a 4.7 per cent. solution of glucose render them agglutinable by normal serum, but that the injection of a glucose solution intraperitoneally calls forth the production of non-specific agglutinins for the same organisms.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 200. Active Immunization against Scarlet Fever.

C. C. YOUNG and P. F. ORR (*Journ. Amer. Med. Assoc.*, May 1st, 1926, p. 1340), from a study of 97 persons shown to be susceptible to scarlet fever by the Dick test, in whom the dosage as well as the time interval between the injections was varied, found that just as great or greater immunity was produced with three injections as with the five injections of scarlet fever toxin recommended by the Scarlet Fever Committee. The dosage suggested by the findings was 500, 5,000, and 30,000 skin test doses, with an interval of two weeks between the injections. The time interval of two weeks was important, as there was less systemic reaction and greater immunity produced than with the usual one week interval. No injurious effect followed the relatively large dose of toxin used in the third injection.

201. H. SPANROW (*C. R. Soc. de Biologie*, July 9th, 1926, p. 395) has performed the Dick test on 12,426 children from sixty-four primary schools in Warsaw. All those reacting positively were submitted to active immunization. The reading of the test gave rise to trouble. It was found that the number of pseudo-reactions varied with each batch of toxin, and that frequently a pseudo-negative reaction with one batch became a positive with another. For this reason it was decided to regard all children giving a positive, a pseudo-positive, or a pseudo-negative reaction as susceptible to scarlet fever, and to vaccinate them accordingly. Three injections of vaccine, prepared according to Dick's original method, were given at about a week's interval. Two months afterwards the Dick test was again performed on all who had been vaccinated to ascertain what proportion had become immune. The results were as follows: Altogether 9,708 children were tested by the Dick method; of these 55.1 per cent. reacted positively. The number of susceptibles who were vaccinated and examined later for susceptibility was 3,385; of these 29.6 per cent. were Dick-negative two months later, 34.8 per cent. were weakly positive, and 35.6 per cent. were still definitely positive. That is to say, about one-third were no longer susceptible, one-third were still slightly susceptible, and one-third remained susceptible, though not necessarily as much as before. Of this last group a certain number appeared to be absolutely unresponsive to vaccination; their Dick reactions remained strongly positive. These patients the author regards as non-immunizable; they constitute about 8.5 per cent. of the whole and correspond to the proportion of similarly unresponsive children observed by Zingher.

### 202. Sequels of Cerebro-spinal Fever after Serum Treatment.

S. McLEAN and J. P. CAFFEY (*Med. Journ. and Record*, May 19th, 1926, p. 702) report their observations on 97 cases of meningococcus meningitis treated with serum at the Babies' Hospital, New York, from 1916 to 1926; 59, or 61 per cent., of the infants recovered. These cases were all of the sporadic type, as the disease had not appeared in epidemic form in New York City during this period. Before the introduction of antimeningococcal serum the mortality of meningococcal meningitis in the first year of life approached 100 per cent., whereas approximately 50 per cent. of the children of this age treated by the authors recovered. In children between 1 and 5 years of age 85 per cent. recovered and 44 patients were followed up for a period ranging from one to ten years. In 9 cases the following serious sequels were obtained: deaf-mutism in 4, hydrocephalus in 2, visual impairment in 2, and mental deficiency in 1 case. Five patients died during the period of observation; 30 were alive and normal in every respect at the time of writing. Of 11 cases in which serum was injected into the ventricles or cisterna magna on account of obstruction of the subarachnoid space 8 made a complete and permanent recovery.

### 203. Obesity of Syphilitic Origin.

BONILLA (*La med. Ibera*, May 29th, 1926, p. 636) states that some writers, especially followers of Castaigne, assert that endocrine obesity is of syphilitic origin. The endocrine character is most pronounced in obesity of pituitary origin, of which acquired or congenital syphilis may be the cause. Clinically endocrine changes of syphilitic origin are most frequently found in the form of infantilism, diabetes insipidus, and obesity. The pituitary nature of obesity has been pointed

out since 1914 by von Noorden, who also drew attention to the frequency of syphilitic pituitary obesity, which may sometimes be favourably affected by arsenical treatment. Bonilla has recently observed two cases of pituitary obesity: One patient, who weighed 133 kg., showed an obesity of pituitary distribution, a basal metabolism of -3 per cent., and an abnormal sella turcica on x-ray examination. The second patient was a girl of 18, weighing 120 kg., with -5 per cent. basal metabolism, and an abnormal sella turcica. Under antisyphilitic treatment she lost 30 kg. in three months, and the basal metabolism rose to +6 per cent. In both cases the genital functions were normal, so that the obesity was purely pituitary.

### 204. Acute Coronary Occlusion.

LOUIS WOLFF and P. D. WHITE (*Boston Med. and Surg. Journ.*, July 1st, 1926, p. 13) report twenty-three necropsies on patients with acute coronary occlusion, and review the literature on this subject. They include all cases of sudden occlusion, in which, as a rule, cardiac infarction occurs, and exclude gradual occlusion. They agree that the disease is common and is now being recognized with increasing frequency, but many practitioners are not aware that the diagnosis can be made during life. As a rule the clinical picture is distinctive, but the triad of pain and pulmonary and gastro-intestinal symptoms does not always occur or may be insufficiently marked for diagnostic purposes unless great care is taken in the examination. For instance, pain may be absent and dyspnoea may be the only symptom; sometimes the pain is intermittent and collapse may be the sole symptom present. Congestive failure following shortly after anginal pain and post-anginal impairment of reserve are strong indications of occlusion. The attack may follow an infection or be post-operative; it may appear during convalescence from illness and while the patient is resting or sleeping in bed. Apparently rapid recovery is a very important feature. Peripheral embolism occurred in 10 per cent. of the cases reported, cardiac infarction in 74 per cent., pericarditis in 48 per cent., and cardiac aneurysm in 13 per cent. As a rule the diagnosis from angina pectoris presents little difficulty, but there is an intermediate group in which prolonged pain is associated with some mechanism other than organic coronary obstruction, or where the adequacy of the collateral circulation precludes infarction except on a small scale, so that the usual clinical features of extensive coronary occlusion are lacking.

## Surgery.

### 205. Adenocarcinoma of the Thyroid Gland.

H. KLOSE (*Zentralbl. f. Chir.*, July 3rd, 1926, p. 1691) remarks that when the question of thyroidectomy has to be considered the possibility of malignant degeneration of a goitre in a middle-aged or elderly patient must not be forgotten. He relates the case of a man, aged 50, for whom thyroidectomy had been recommended for the relief of pressure symptoms. The right lobe of the thyroid gland appeared to be normal, but the left was nodular. Skiagrams showed a distinct deviation of the trachea to the right. The gland, though mobile, was very hard, but no enlarged lymph glands could be felt. A pleural effusion was present on the right side, and a skiagram of the right lung showed a large circular shadow of a metastasis, while on the liver margin a nodular tumour as large as a fist could be felt. In spite of the absence of enlarged lymph glands, the mobility of the thyroid, and the patient's good general health, it was evident that there was a primary malignant growth of the thyroid with metastases in the lung and liver. The thyroid was removed on account of the danger of asphyxia and proved to be an adenocarcinoma.

### 206. Indications for Cholecystectomy.

A. O. WHIPPLE (*Amer. Journ. Surg.*, June, 1926, p. 129) discusses the question whether a diseased gall bladder should be drained or removed, and states that the indications for cholecystectomy can only be determined by a careful comparison of pre-operative with post-operative data. He has traced the after-history of 170 patients who were found to have gall stones at operation; 90 per cent. were entirely relieved of pain by cholecystectomy. In 47 non-calculous cases 76 per cent. were relieved of their symptoms by this operation. The calculous cases gave, therefore, far better results. Whipple

thinks that this is due to the more striking symptoms caused by gall stones, and to the fact that they set up inflammation in most cases. Calculous cholecystitis treated by cholecystectomy gives good results, and a low risk if the operation is performed before the disease has passed the cystic duct, but dire consequences follow when involvement of the common duct makes surgical treatment urgent. Non-calculous cases offer a different problem, and it is essential to make sure there are no stones at operation. The author advises that if the gall bladder does not empty on pressure the bile should be aspirated; if the gall bladder empties easily but is thickened and has enlarged glands it is better to remove it. The gall bladder should be drained in acute severe inflammation, if there is oedema of the pancreas and the possibility of cancer of the common duct. Whipple adds that it is poor surgery to remove a gall bladder merely because it is in the field of operation.

#### 207. The Closure of Faecal Fistulas.

X. DELORE, P. MALLET-GUY, and A. VACHEY (*Rev. de Chir.*, No. 4, 1926, p. 259) recommend the intraperitoneal method of closing faecal fistulas as the result of employing it in a considerable number of cases. Where an abscess cavity was also present this was opened up and thoroughly drained at a preliminary operation. A sufficient period should be allowed to determine whether the fistula will close spontaneously; when after several months this appears unlikely, operation is indicated. The skin is incised around the fistula and the aponeurotic and muscular planes carefully defined. The peritoneum is exposed and opened at one extremity of the incision. The index finger of the left hand is inserted at this spot and the peritoneum freed all around the fistula. The gut is thus freed, brought up into the wound, and carefully examined. When there is much loss of substance and a large opening in the intestine enterectomy may be necessary. In less severe cases enterorrhaphy may be carried out. The latter procedure can be employed in the great majority of cases, and the opening is sutured with three layers of catgut sutures. Where enterectomy is performed the gut is brought together by an end-to-end anastomosis. The abdominal wall is closed in layers as far as possible, and a drain is usually placed in the centre of the wound. The fingers and the scissors play the great part in the operation, and their use renders the procedure free from risk of further injury. The authors think that this method gives better results with less risk than any other operation.

#### 203. Cancer Statistics in Norway.

F. G. GADE (*Norsk Mag. f. Laegevid.*, July, 1926, p. 559) states that during the quinquennium 1919 to 1923 there were 14,164 deaths from cancer in Norway, giving an average cancer mortality of 10.75 per 100,000 population, as compared with a cancer mortality of 9.53 during the period 1902 to 1911. This increase in the mortality, Gade thinks, may be due partly to the increase in the number of medical practitioners during this period—namely, from 1,084 to 1,548—and a consequently better detection of the disease, and partly to the increase in the average age of the population, which has risen from 48.73 for men and 51.27 for women in 1881 to 1890 to 55.62 for men and 58.71 for women in 1911 to 1920. The influence of age upon the development of cancer was certain, 67.8 per cent. of all deaths from cancer occurring after the sixtieth year among only 11 per cent. of the entire population. In persons above the age of 40 there was sixty-three times as much cancer as in the population below that age. As regards sex, females showed a slight preponderance (52.4 per cent.) over males (47.6 per cent.) when the whole population was taken into account. The organs most frequently affected were the stomach with 51.66 per cent. of all cancer deaths, the female generative organs with 12.07 per cent. (uterus 6.19, ovaries 0.94, breast 4.94 per cent.), prostate 1.48, and skin 1.43 per cent. Sarcomata formed 5.49 per cent. of all malignant tumours.

#### 209. Diagnosis of Intestinal Perforation.

J. SABRAZES (*Gaz. hebdom. Sci. Méd. de Bordeaux*, June 27th, 1926, p. 402) maintains that the presence of intestinal spiral micro-organisms (spironemata and treponemata) in the peritoneal fluid is a sign of intestinal perforation. In typhoid and paratyphoid fevers the organisms are present in Peyer's patches, and when perforation occurs they escape into the peritoneal cavity, where conditions are favourable for their rapid multiplication. On laparotomy for a supposed perforation the peritoneal fluid should at once be examined for the presence of spirochaetes; their absence indicates that perforation has not occurred. Apart from typhoid and paratyphoid fevers examination of the peritoneal fluid for spirochaetes should also be made in other cases of intestinal or appendicular perforation and affections of the pylorus, pancreas, and gall bladder, as well as in abdominal wounds when perforation is suspected.

## Therapeutics.

#### 210. Stovarsol in General Paralysis.

A. SZÉZARY and A. BARBÉ (*Presse Méd.*, July 7th, 1926, p. 849) publish their experience in the treatment of general paralysis by stovarsol; they chose this pentavalent preparation of arsenic since it only acts after reduction. The patients, 50 in number, were all well marked cases and were nearly all much improved in their general health; in 12 cases the total results, including the mental state, were excellent, and the patients were able to return to their work. In 14 of the 50 cases the results are described as very good, in 4 as passable, in 6 as moderate, and in 26 there was no change. Details are given of 10 of the cases. The authors found that the degree of clinical improvement was not correlated with the extent of change in the spinal fluid. The abnormal characters of this fluid never completely disappeared, although they often diminished. Stovarsol appears to act rather as a general stimulant of the haemopoietic organs than as a spirillicide, and can be compared with the treatment by malaria. On the whole the drug was well borne, but optic neuritis followed in four cases.

#### 211. The Therapeutic Value of Ichthylol.

A. KISSMEYER (*Ann. de Derm. et de Syph.*, May, 1926, p. 297) thinks that the action of ichthylol on the skin is not quite clear; while it is a feeble reducing agent, thus increasing keratinization, it is also a vaso-constrictor and has bactericidal properties, but whether these properties are due to its sulphur content or to other chemical agents contained in the bituminous oily base is not known. These effects are produced by rather feeble doses, such as dilutions of 2 to 10 per cent. In stronger doses, or when applied undiluted, it has a definite action on the deeper layers of the skin; it is very definitely resolvent and antiphlogistic in both cutaneous and subcutaneous inflammation, such as bubo, epididymitis, and inflammation of the axillary sweat glands. A 10 per cent. glycerin solution is much used in gynaecological cases. Ichthylol ointment is useful in chilblains, prurigo, erysipelas, and acute eczema. The author considers that the deletion of ichthylol from the United States Pharmacopoeia was due to failure to appreciate its specific effects in dermatology. He has found it particularly useful in furunculosis, when used as suggested by Unna, either in ointments or in aqueous solutions; its viscosity makes it particularly useful in the treatment of ambulant cases. The boil and the surrounding skin should be washed with alcohol or with tincture of iodine. Pure ichthylol is then applied with a pledget of cotton-wool, or painted on the surrounding skin over an area of 2 cm. with a camel's hair brush. The boil and the surrounding skin are then covered with a thin layer of cotton-wool saturated with ichthylol; this dressing adapts itself and adheres closely to the skin. After a few minutes the patient can dress without displacing the ichthylol pad. Next day the dry pad is removed by bathing with tepid water, and if the boil has not discharged the treatment is repeated. In freely discharging boils the dressing should be renewed twice a day. In large boils and carbuncles incisions should be avoided when evacuation of pus is indicated; it is better to use Paquelin's thermo-cautery or the galvano-cautery. In many cases the early application of ichthylol causes resolution of the boil without suppuration.

#### 212. Treatment of Pyelitis in Infants.

M. LAVERGNE (*Le Nourrisson*, May, 1926, p. 137) remarks that untreated pyelitis in infants may clear up in four to six weeks, but energetic treatment is indicated to prevent a chronic condition developing. Milk forms the ideal diet, and in older children eggs should be avoided. Urinary antiseptics, though indicated theoretically and generally given, do not seem to do much good. In Holland large doses of potassium citrate, 10 to 20 grams a day for nurslings, are administered to alkalinize the urine. This treatment is interrupted for periods of acid medication. Vaccine therapy, especially with autogenous vaccines, gives good results, though not invariably; the dose should be small and the local and general reactions should be slight. Injections are given every two or three days in doses ranging from 10 to 50 million per c.c.m. and should be continued for some time after the disappearance of pyuria. The coli-soda vaccine of Mauté can be given by the mouth. Lavergne adds that unfortunately therapeutic immunization with the bacteriophage presents great practical difficulties. It is necessary to isolate a bacteriophage that lyses the colon bacillus pathogenic to the particular patient. A bacteriophage which does not lyse *in vitro* will not cure in the living. But if a suitable bacteriophage is found cure is obtained in a few days in 80 per cent. of the cases. The bacteriophage is administered simultaneously by the mouth and by hypodermic injection; when possible it is also introduced into the bladder. Only two or three injections are

# EPITOME OF CURRENT MEDICAL LITERATURE.

given, for fear of sensitizing instead of immunizing the patient. In cases of obstinate pyelitis the possibility of a local lesion should be kept in mind, congenital usually; treatment should be directed to the cause. Reinfection may occur from the blood stream, so that a pyelonephritis may reappear after apparent cure. It is not the kidney that is at fault but the intestine. Purgation should be sought for, at least but the intestine with worms should be sought for. Older infants infestation with worms should be sought for. Collargol, 2 drachms of a 1 in 50 solution daily, has proved of value as an intestinal antiseptic. Some preparation of lactic ferments should also be given, or lactic bacilli mixed with paraffined starch. The author advocates spa treatment to complete the cure in older infants.

## 213. The Use of Vitamins in Therapeutics.

F. CASCELLA (*La Pediatria: Archivio di Pat. e clin. ped.*, Vol. 2, Fasc. 1, p. 49) considers that vitamins act as catalysing agents which display activity and are subsequently eliminated. He discusses their mode of action pharmacologically, in pathological conditions, together with their therapeutic value, and in the metabolism of proteins, carbon dioxide and the blood sugar level, fats, salts, and reencapsulation within the body. In his investigation 25 babies of both sexes, aged from 1 month to 3 years, were placed in three groups, and each was treated with two drachms of isolated vitamins by mouth and one intramuscular injection daily, continued over a period of three months without other treatment. In all the Wassermann test was performed, and in most a red cell count and haemoglobin estimation. The first group consisted of cases of remote disturbances or latent deficiency—pallor, hypotonia, mild digestive disturbances, under-weight, malnutrition, and retarded development. Two patients reacted slowly to treatment and subsequently developed mild rickets; Cascella attributes this to constitutional inability to assimilate the vitamins. The remaining children showed marked improvement. The second group contained cases of typical deficiency disease. The children in both of these groups showed immediate arrest of disease, rapid improvement and retarded development following upon tuberculosis, syphilis, enteritis, pneumonia, and furunculosis, similarly treated, the method promising results that Cascella considers that the isolated vitamin has an advantage that it can be administered where a food is not tolerated. In Cascella's experience the action of vitamins is controlled and modified by the endocrine glands. He considers that vitamins display their activity by means of hormones.

## Radiology.

### 214. X-ray Treatment of Cerebral Tumours.

H. SÆTHRE and R. R. JØRGENSEN (*Norsk Mag. f. Lægevid.*, June, 1926, p. 425) treated by x rays eleven cases of cerebral tumour, all but one of which had been previously trephined. In six cases the diagnosis had been confirmed (in three by microscopic examination of the brain, in two by operation, and in one by x rays). Of the five in which the diagnosis was not established one was probably a case of cortical epilepsy, and the other four showed on operation a considerably increased intracranial pressure, atrophy of the cranial bones being shown on x-ray examination. The results of treatment were as follows: Among the six cases in which the diagnosis of cerebral tumour was confirmed two died, both from nine to twenty-four months after discharge from hospital. Of these one was a case of myxo-fibrosarcoma of the right upper temporal convolution, in which recovery had apparently taken place with only slight defect of vision in one eye. X rays on admission showed an orange-shaped shadow and a defect of the frontal lobe. Recovery in this case had also apparently occurred apart from blindness in the right eye which was present on admission. The third case was an infiltrating tumour of the parieto-temporal region (sarcoma or glioma). The patient was healthy and free from symptoms two years later. The fourth case was a haemangioma of the precentral convolution, in which improvement was obtained. Of the five cases in which the diagnosis of cerebral tumour was not verified that made considerable improvement as the result of x-ray treatment. The authors maintain that this treatment should only be employed when radical operation is not practicable—that is to say, in those tumours which cannot be localized or removed except partially. Even when the histological structure of the tumour is known it is impossible to foretell

whether the x-ray treatment will be of use or not, especially as the same tumour may show a different sensibility towards x rays at different periods. The authors emphasize the necessity for trephining before x-ray treatment in all cases where signs of increased pressure are present, otherwise the rise of brain pressure caused by x-ray treatment may be fatal.

### Cholecystography.

215. F. S. EYELETH (*Boston Med. and Surg. Journ.*, July 22nd, 1926, p. 165) emphasizes the diagnostic importance of recent developments in cholecystography following the introduction of the sodium salt of tetraiodophthalein. This dye, which renders possible a direct view of the gall bladder, reveals opaque stones and non-opaque ones when surrounded by bile; it enables the position, shape, size, and emptying power of the gall bladder to be ascertained. Of the three methods of administration of the salt, intravenous, jejunal, and oral, the latter is the more generally used. The preparation of the patient is important, a laxative being given two days before, and not on the day when the dye is administered; a radiogram should also be taken for purposes of comparison. About three hours after a light supper containing fats the salt is given in 5-grain capsules every fifteen to thirty minutes with plenty of water up to an average dose of 40 grains for 150 lb. body weight; no more food is taken until after a cholecystogram twelve to eighteen hours later, by which time the dye will have reached the gall bladder. A meal rich in fats is then given and the gall bladder will be seen to diminish perceptibly in one and a half to two hours. Eyeleth uses kerosol capsules, which are treated to resist the acid of the stomach and to dissolve readily in the intestinal tract, so that the dye is taken up by the portal veins. Essentials for success are accuracy of technique, excretion of the dye by the liver, patency of the hepatic, cystic, and common ducts, and ability of the gall bladder to empty and fill itself, concentrate the dye, and hold sufficient to give rise to a shadow. Contradictions of the method are obstruction of the common duct, extensive hepatic disease, marked diabetes, hyperthyroidism, arterio-sclerosis, cardiac disease, hyperadvanced hepatic cirrhosis, and pregnancy. Usually no reaction follows administration, but about 12 per cent. of the patients complain of temporary nausea, vomiting, or diarrhoea.

### 216. Radio-Diagnosis of Late Cranial Syphilis.

A. LÉRI and P. COTTENOT (*Presse Méd.*, June 26th, 1926, p. 801) publish a series of radiograms of the vault of the skull showing various syphilitic lesions of the internal table. These lesions take three forms—gumma, ulceration, and hyperostosis, singly or in combination—and the authors describe the different radiographic appearances of each type of lesion. Nine radiograms with diagrammatic outline are given to illustrate the various types, and details are supplied of several cases much improved by specific treatment and where with a negative Wassermann reaction a definite lesion of syphilitic history the radiogram revealed a definite lesion of the internal table. In many cases epileptic fits, hemiplegia, and persistent headaches were recognized as due to osseous lesions of the internal table, and in some cases were quickly relieved by specific treatment. The radiographical procedure for displaying lesions of the vault differs from that required for the base of the skull, photographs being taken in various positions of flexion and extension of the head. The authors believe that a valuable aid to diagnosis is provided by their method.

## Obstetrics and Gynaecology.

### 217. Ante-partum Accidental Haemorrhage.

G. FITZGIBBON (*Journ. Obstet. and Gynaecol. of Brit. Empire*, Summer No., 1926, p. 194) discusses the nature and treatment of ante-partum accidental haemorrhage, and distinguishes two types; in the first the bleeding is due to simple and truly accidental ablation of part of the placenta, and in the second to a toxæmic condition due to haematoma or apoplexy of the uterine wall and following chronic nephritis. When there is external bleeding the fluid is dark and does not clot, being the haemorrhagic serum expressed from coagulated blood which is retained in the uterus or in the uterine wall. The muscle fibres are healthy and there is no rapid bleeding at any time. FitzGibbon considers that treatment should be directed towards restoring the enfeebled circulation, the labour being allowed to terminate naturally, which will involve most cases occur spontaneously after recovery from the collapse. This haematomatous condition of the placental site, which does not originate in the placental site. With a live foetus the patient is treated on palliative and expectant

lines and allowed to complete labour without intervention, but if the uterus is tense and painful the membranes are punctured. Intravenous saline injections may be needed if collapse is severe with the induction of labour after recovery. If the foetus is dead labour must be induced; the uterus is controlled and ergotin and pituitrin are given, though FitzGibbon has never seen any indication of post-partum haemorrhage. Plugging the vagina is not indicated, since the bleeding is believed to be due to a slow percolation, and the author considers Caesarean section totally wrong for a rapid and persistent bleeding, its results being worse than those afforded by any other form of treatment. In support of these views FitzGibbon gives the results of his treatment in sixty-four consecutive cases with three deaths, one of which followed hysterectomy; he considers that a patient who cannot recover from collapse is also incapable of surviving hysterectomy.

#### 218. A Manoeuvre in High Forceps Delivery.

LANTUÉJOL (*Gynæcol. et Obstét.*, 1926, xiii, 5, p. 343), while agreeing that application of forceps to the foetal head at the brim of the pelvis is very rarely justifiable, remarks that occasionally the surgeon is impelled to try it. He describes a device which he has found useful in difficult cases of this operation and which consists in rotating the pubic symphysis around the foetal head, which is drawn downwards and fixed by traction on the forceps. The blades are applied with the patient in the Crouzat-Walcher position, with the thighs hyperextended and hanging over the edge of the couch; while traction is maintained the thighs are very gently and slowly flexed on the abdomen by assistants, the manoeuvre being repeated if necessary. The distance from the sacral promontory to the subpubic region is about 7 mm. greater with the thighs hyperextended than flexed. Observing the mechanism in the cadaver, Lantuéjoul in conducting delivery by the device described has seen the symphysis turn around the anterior parietal bone, the posterior parietal bone being still above the promontory. Engagement is made by anterior asynclitism. Immobilization of the head during movements of the pelvis demands less force, it is said, than mobilization of the head in a free pelvis, but gentleness in flexing the thighs is very necessary. Four cases of successful use of the device in normal pelvis are recorded; version appeared to be contraindicated after prolonged labour by reason of early rupture of the membranes and escape of the major portion of the liquor amnii.

#### 219. Resistance of the Ovary to Abortifacient Operations.

S. WEISSENBERG (*Zentralbl. f. Gynäk.*, May 8th, 1926, p. 1263) reports that four patients in Russia, after instrumental attempts on the part of physicians to induce abortion from the sixth to eighth week, were found, two or three months later, still to possess a living foetus, which was born alive at term. A fifth woman was found to have a living foetus nineteen weeks after an attempt to induce abortion six weeks after the last menstruation; in the interval there had been several returns of haemorrhage, and eventually the patient was confined prematurely in the sixth month. Weissenberg thinks that the probable explanation lies in the resistance offered by the early ovum, and especially by the amniotic sac. In another case, during an operation ten days after a previous attempt to induce abortion at the sixth week, it was demonstrated that the uterus had then been perforated behind and above the internal os; the pregnancy was allowed to continue until the fourth month. An instance is mentioned in which an ovum, possibly embedded in a tubal isthmus, evaded thorough curetting five days after a missed menstruation; nineteen days later uterine pregnancy was clinically demonstrable, and confirmation was obtained at a second curetting shortly afterwards.

## Pathology.

#### 220. Importance of Symbiosis in Certain Diseases.

A. CASTELLANI (*Journ. Amer. Med. Assoc.*, July 3rd, 1926, p. 15) defines the term "symbiosis" broadly as the living together of two organisms in close association without detriment to either, and with mutual benefit. An important part is played by symbiosis both in the nutrition of plants and in the germination of certain seeds. As an example of symbiosis between two vegetable plants the author cites the lichens, and of symbiosis between plant and animal he instances the marine worm *convoluta* and its contained alga. Certain nodules found in the roots of plants are now known to be formed by bacteria which derive carbohydrate nourishment from the host plant, and in turn supply the plant with nitrogen. The germination of seeds of some plants, such

as orchids, can only occur in the presence of appropriate fungi. Castellani also points out the importance of symbiosis in fermentation phenomena, and describes his experiments with the various yeasts to show that the production of gas is due to allied bacterial action. More recently he has experimented with pathogenic bacteria and a pathogenic yeast *Cryptococcus graciloides* and with non-gas producing organisms such as *B. dysenteriae* Flexner, combined with the Morgan bacillus on maltose; acidity and gas resulted from the combination, although the latter bacillus produces neither alone. In a similar way, he thinks, the association of organisms has a determining influence in the etiology of certain diseases and the causation of certain symptoms. As an example of the former he quotes the association of a fungus (*Nocardia*) and a coccus (*Micrococcus nigrescens*) in the production of the disease of the hair termed trichomycosis nigra; and he similarly assigns trichomycosis rubra and a variety of stomatitis known as stomatis cryptococco-bacillaris to other combined agencies. He adds that the mousy smell of favus is not caused directly by the fungus but by associated organisms, and in enteric fever the abdominal distension, although in part due to defective tone in the intestinal walls, is certainly not set up by the typhoid bacillus of itself, but in association with certain bacilli such as *B. mergani*.

#### 221. The Characters of the Enterococcus.

S. V. BAGGER (*Journ. Path. and Bact.*, July, 1926, p. 225), at Copenhagen, has examined 150 strains of enterococci; of these, 58 were isolated from the normal intestine and 92 from cases of acute appendicitis. Morphologically the individual cocci were oblong or rhomboid; they were arranged in pairs, either in direct line or, more frequently, at an angle to each other, so that a single pair resembled the French circumflex accent. The optimum hydrogen-ion concentration for growth in broth was about pH 7.5; the range within which growth occurred varied between pH 5 and pH 10. The change in reaction produced by growth in broth was remarkably small, being generally less than pH 0.2. Gelatin was liquefied by 10 per cent. of the strains. Growth occurred from about 8° C. to about 48° C., and was apparently as luxuriant under strictly anaerobic conditions as in the presence of air. The organisms were able to grow satisfactorily in pure ox bile containing 1 per cent. peptone; in this medium other streptococci failed to multiply. A very thorough study was made of their resistance to heat. The cultures—twenty-four hours old and pH 7.5—were placed in 1 c.cm. ampoules, which were then sealed and immersed in a water bath. After one hour a loopful of the culture was transferred to an agar plate, which was incubated at 37° C. for two days. It was found that all the strains withstood a temperature of 58° C. for one hour; 95 per cent. survived a temperature of 60° C., 67 per cent. a temperature of 62° C., and 3 per cent. a temperature of 65° C. for the same period. Their resistance to antiseptics was likewise high; all withstood the action of 0.5 per cent. phenol for twenty-four hours at 37° C., but were uniformly killed by 1.5 per cent. phenol. All resisted 0.1 per cent. formalin for twenty-four hours at 37° C., but were killed by 0.3 per cent. formalin. No strains formed indol. The common sugars fermented were glucose, maltose, mannite, lactose, sucrose, and salicin. A study was made of the action on the rarer sugars and a tentative classification based on the results. Agglutination was of no help in classifying them, since they were characterized by strain specificity. Intravenous injections of 1 c.cm. of a broth culture sometimes killed rabbits. Intraperitoneal injections of the same amount generally killed mice, but never guinea-pigs.

#### 222. A Possible Cause of Appendicitis.

M. WEINBERG and A.-R. PREVOT (*C. R. Soc. de Biologie*, July 23rd, 1926, p. 519) describe an organism, isolated from six cases of appendicitis, which they claim plays an important role in this disease, and which they name *Esobacterium biacutum*. It is a rod-shaped, Gram-negative bacillus with tapering ends, measuring 1.4 to 1.8  $\mu$  in length and 0.4 to 0.5  $\mu$  in breadth, and arranged in diplo- and streptobacillary forms. It grows well in sugar bouillon and peptone water, and in deep agar cultures forms gas. This bacillus is not proteolytic, does not liquefy gelatin, nor act on milk-clot or coagulated white of egg. Litmus milk is coagulated with the formation of a soft clot. Glucose, levulose, lactose, maltose, and galactose are fermented by it. *E. biacutum* grows well in bile with added bouillon, but not in bile alone; it does not produce indol. In liquid media small quantities of sulphuretted hydrogen are formed, and deep agar cultures, with the addition of subacetate of lead, are turned black. These bacilli possess no haemolytic power *in vitro*, but produce haemorrhagic lesions in inoculated animals, and they are pathogenic for guinea-pigs. Serums from inoculated dogs agglutinate not only the homologous strain used, but also the five other heterologous ones.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 223. Immunization against Diphtheria.

G. RAMON (*Archiv. de l'Inst. Past. d'Algérie*, 1926, 4, p. 61) gives a review of the method of immunizing children against diphtheria by means of formalized toxin. If 4 c.cm. of commercial formalin are added to a litre of diphtheria toxin, and the mixture is incubated for a month at 37° C., it will be found that though the flocculating power of the toxin is unaltered its toxicity has disappeared. One or more c.cm. of this formalized toxin may be injected into guinea-pigs without producing any sign of intoxication: an untreated serum, on the other hand, will cause death in a dose of 1/1000th c.cm. The author has used this formalized toxin for immunizing children who give a Schick positive reaction. He gives three injections of 0.5 c.cm., 1 c.cm., and 1.5 c.cm., separating the first two by an interval of three weeks, the second and third by an interval of a fortnight; by this means he was able to render 98 per cent. of his subjects Schick negative in six weeks. He thinks that the best age for inoculation is 2 to 5 years, the age of greatest susceptibility to diphtheria, but it may be performed at any time of life. The duration of the immunity that follows is not yet known, but there is reason to think that it is permanent.

224. P. HARVIER and T. RIQUIN (*Paris Méd.*, May 8th, 1925, p. 456) report their observations on 88 children under 11 years old inoculated with anatoxin against diphtheria. Children with a positive Schick reaction were given a first injection of 0.5 c.cm. of anatoxin, and three weeks later a second injection of 1 c.cm. After two injections 84 out of the 88, or 95.4 per cent., became immune. The reactions were of two kinds: a slight local inflammatory redness, heat, and tenderness of the skin over an area of 1 to 3 c.cm., or the production of a red patch with swelling and a rise of temperature to 102°. These severe reactions were observed almost exclusively in children above 7 years of age. The authors suggest that leave should be obtained from the parents to inoculate all children between 2 and 7 years of age. Diphtheria chiefly affects children before the age of 8, and severe anatoxin reactions are quite exceptional before the age of 7. Two injections of anatoxin (0.5 and 1 c.cm.) may be given with three weeks' interval between each; a third injection of 1 c.cm. is only required in exceptional cases (5 per cent.) in which the Schick reaction remains positive after the second injection. Alternatively each child may be given three injections of anatoxin (0.5, 1, and 1 c.cm.) with three weeks' interval between each; immunity is said to be obtained by this method in 98 per cent.

225. H. NOTHMANN (*Arch. f. Kinderheilk.*, June 4th, 1925, p. 112), after inoculating 260 children, aged from 10 months to 8 years, with toxin-antitoxin, concludes that the method is free from danger if a reliable preparation is used, but that in about 10 per cent. local and general reactions follow, even among carefully selected children aged from 1 to 6 years, the frequency of the reactions increasing with advance in age. The occurrence of the reactions appeared to be due to a constitutional anomaly, such as an obvious or latent exudative diathesis, tuberculous infection, neuropathy, or severe rickets. Nothmann mentions the following contraindications to the employment of toxin-antitoxin: tuberculosis, the exudative diathesis, neuropathy, disease of the sympathetic nervous system, kidneys, and heart, psychical abnormalities, convalescence from acute infections, and all states which suggest an increased susceptibility to the diphtheria toxin or other substances contained in the toxin-antitoxin. A positive tuberculin reaction, without clinical evidence of tuberculosis, is not regarded as a contraindication.

226. H. ALDERSHOFF (*Nederl. Tijdschr. v. Geneesk.*, June 19th, 1925, p. 2638), in a previous paper, reported that Ramon's anatoxin, when diluted so as to produce no troublesome non-specific reaction, conferred only an incomplete immunity (*Epitome*, September 19th, 1925, para. 216). He now states that he has made a refined underneutralized mixture of antitoxin and anatoxin, to which he has given the name "ananti". He claims that this new preparation is an almost protein-free vaccine against diphtheria, which causes no non-specific reaction, and is therefore free from that property which gives so much trouble to adults. The time required to produce immunity by inoculation with "ananti" is said to be

equal to that taken by toxin-antitoxin, but by injecting the large doses rendered possible by the absence of toxicity and of non-specific reactions this time can be shortened.

### 227. Sudden Onset of Typhoid Fever in Children.

P. NOBÉCOURT (*Journ. de Méd. de Paris*, May 24th, 1926, p. 441) records two illustrative cases, in children aged 3 and 6 years respectively, in whom the onset of typhoid fever simulated pneumonia in one case and bronchopneumonia in the other; it was only on the ninth or tenth day that the correct diagnosis was established by the appearance of rose spots. While a sudden or rapid onset of typhoid fever is rare in the adult, it is fairly frequent in children, being met with in 11.9 per cent., according to Hutinel and Darre, though Nobécourt thinks that the real frequency is greater still. It is probable that the disease has been in existence for some days before obtrusive symptoms arouse attention. These symptoms may involve the digestive system, and the disease may then simulate tonsillitis, appendicitis, or peritonitis; or the respiratory system may be affected so that the diagnosis made is bronchitis or bronchopneumonia; or the first symptoms may be those concerned with the nervous system, so that the child is thought to be suffering from cerebro-spinal fever or even sciatica. According to Nobécourt, a sudden onset does not necessarily indicate a severe attack, but it is fairly often a sign that the disease may be long and severe.

### 228. Argyll Robertson Pupil in Epidemic Encephalitis.

P. MÉRÉL (*Gaz. d'Hép.*, July 7th, 1926, p. 870), who records an illustrative case, states that numerous writers have drawn attention to changes in the pupils occurring in epidemic encephalitis, either in the form of paralysis of accommodation or complete immobility of the pupils. Achard regards the Argyll Robertson pupil as very rare in this disease, but the reverse process—namely, loss of accommodation and preservation of the light reflex—as comparatively frequent. Mlle G. Lévy holds the same opinion. Wimmer, who has seen a very large number of cases of epidemic neuraxitis, has never observed an example of Argyll Robertson pupil in this condition, though he has often met with complete immobility of the pupils. Krabbe, however, in 1925 recorded a syphilitic encephalitis in which he observed a pupil. Méré's case was in a man, aged 25, in whom the Wassermann reaction in the blood and cerebro-spinal fluid was negative, and examination of the cerebro-spinal fluid did not show any trace of syphilis of the nervous system. According to the work of Duverger and Redslob, the Argyll Robertson pupil appears to be merely an incomplete paralysis of the iris in which the light reflex disappears first, while the accommodation reflex persists. This theory explains why this sign appears in iritis, glaucoma, traumatic and syphilitic lesions involving the ophthalmic ganglion, in central lesions of the cerebral peduncles, tuberculous of the corpora quadrigemina, and cerebral tumours.

### Functional Disorders of the Heart.

229. P. D. WHITE (*American Heart Journal*, June, 1926, p. 527) states that functional disorders of the heart are very common; they are more frequently found without than with organic heart disease. Usually the disturbance is so slight—being due to an effort syndrome or to extra-systoles—that advice is not sought, and their great frequency is not recognized. Important functional disorders such as auricular fibrillation, heart-block, or congestive failure are much more common in cases of organic disease. The author summarizes the records of 1,500 consecutive private patients. Effort syndrome was most common and occurred five times more frequently in the functional cases: extra-systoles sufficient to attract attention came next, and finally, paroxysmal tachycardia was found twice as often without as with clinical signs of organic disease. Functional systolic murmurs alone, cardiac "phobias," marked sinus arrhythmia, sino-auricular tachycardia, and sino-auricular bradycardia were less frequent, but together formed an appreciable percentage of the whole series. White finds that of those functional disturbances which occur more frequently than without clinical signs of heart disease, auricular fibrillation (paroxysmal as well as constant) and angina pectoris are the most common and important. Both conditions occur occasionally without any obvious cardiac disease. Auricular flutter is rare, and heart-block, complete failure, and pulsus alternans seldom, if ever, occur without evidence of serious heart disease. Effort syndrome depends upon two factors—inherited neurosis, and

nervous or physical strain. If neither factor is appreciable there will be no effort syndrome; if both are pronounced effort syndrome will be more or less severe; if one or other is negligible the remaining factor must be extreme to produce symptoms. White has obtained no evidence that it leads to organic disease in later life. It is possible that effort syndrome, by forcing the patient to lessen the strain of work and play in youth, may retard the development of serious heart disease and arterio-sclerosis in later life.

### 230. Prophylaxis in Measles.

J. H. TOWNSEND (*Boston Med. and Surg. Journ.*, May 13th, 1926, p. 869) describes the use of prophylactic measures in an epidemic of 63 cases of measles in a boarding school of 400 boys. A dose of 20 c.cm. of blood from an adult who had had measles twenty years previously seemed to have no effect either in preventing or modifying the disease. Blood from convalescents in a dosage of 9 c.cm. of whole blood (5 to 5.5 c.cm. of serum) had little or no effect in preventing infection, but influenced markedly the course of the disease when it was given before the end of the first week of the incubation period, while 32 boys who received convalescent blood at least eight days before the development of the rash showed an average duration of the febrile period of 3.66 days, 21 boys who had no inoculation showed an average duration of the febrile period of 6.45 days. The average maximum temperature of the 32 who received convalescent blood at least eight days before the development of the rash was 102.5°, whereas the average maximum temperature of the 21 who were not inoculated was 103.5°. The average stay in the infirmary of the 32 inoculated boys was 9.7 days, whereas the average stay of the control group was 13 days. No complications occurred in the inoculated group, whereas in the control group there was one case of bronchopneumonia, one of otitis media, one of frontal sinusitis, and one of otitis externa. The mild character of the disease in many of the inoculated was very striking. The inoculations had no after effects whatever. Good results were obtained whether the blood was administered as late as six days after exposure or as early as twelve days before the probable date of infection.

## Surgery.

### 231. Cancer of the Rectum.

J. P. LOCKHART-MUMMERY (*Brit. Journ. of Surg.*, July, 1926, p. 110) records the results of perineal excision of the rectum in a sequence of 200 cases; 123 patients were males, 77 females, and the condition occurred most often between the ages of 50 and 60. He finds that adenomata of the bowel are an important predisposing cause and appear to be a definite precancerous condition. The perineal operation is performed in two stages, a permanent colostomy being followed by a later resection. The patient lies in the semiprone position, the anus is closed, and the coccyx is then excised. The levatores ani are divided close to the pelvic wall, and as much bowel as possible is removed after opening the peritoneum. The total mortality was just over 8 per cent. The author states that nearly 80 per cent. of patients coming for hospital treatment are quite inoperable when first seen. He adds that out of 95 cases operated on over five years ago 45 are known to be cured. Patients live in comfort after the operation, and the only disability is referable to the colostomy. Many were able to return to their former occupation. He concludes that the results compare favourably with cancer of any other organ, and that earlier diagnosis will give material improvement in the proportion of cures following operation.

### 232. Malignant Epithelial Neoplasms in Youth.

L. H. FOWLER (*Surg., Gynecol., and Obstet.*, July, 1926, p. 73), in support of his contention that malignant epithelial neoplasms are much commoner in youth than is generally recognized, states that 112 patients less than 26 years of age with pathologically demonstrated malignant disease were operated on at the Mayo Clinic between January, 1914, and January, 1924. Of these 89 were cases of carcinoma and 23 of epithelioma. The youngest patient was 1 year old. The total known mortality was more than 50 per cent., but 18.7 per cent. could not be traced. Only 14.2 per cent. were alive more than three years after operation. Nearly every organ has been the seat of carcinoma in the young. The rectum and ovary were most frequently involved (14 cases each, or 12.5 per cent.). Carcinoma of the rectum had the highest mortality (85.7 per cent.), with no patient known to be living longer than one year. The other organs were involved as follows: stomach in 9 cases (8 per cent.); thyroid, breast, kidney, in 7 cases each (6.25 per cent.); testis, lip, cervix, in 5 cases each (4.4 per cent.); miscellaneous, in 39 cases (34.8 per cent.). Anaemia

543 B

is a marked feature of carcinoma of the right half of the colon in youth as in adult life. Involvement of the neighbouring lymph glands in carcinoma of the breast and large intestine in youth is a cause of increased mortality. In youth carcinoma of the thyroid is usually found by the pathologist and not by the surgeon; it is intracapsular and its mortality is low. Of the 23 cases of epithelioma 11 were in males and 12 in females; the youngest was 19 years of age. In nearly half the cases the growth was situated in the cervix or lip (5 cases in each). There were 17 squamous-celled and 5 melanotic epitheliomata and 1 non-melanotic epithelioma. Eight patients were dead, 5 were alive from one to three years after operation, 2 were living more than three years, and 8 had not been traced.

### 233. Wounds of the Heart.

C. S. BECK (*Arch. of Surg.*, August, 1926, p. 205) remarks that the successful suture of a wound of the heart is not an uncommon surgical feat. Compression of the organ by the collection of blood in the pericardial cavity is the cardinal sign in the diagnosis of wounds of the heart. Numerous methods for exposure of the heart have been described; the most satisfactory, according to Beck, are the median sternotomy and the left intercosto-chondral thoracotomy. The former provides the best exposure of the heart; the latter of both the heart and the left lung. In median sternotomy the heart is protected by a spatula under the sternum, which is split with a saw. The pleurae are separated and the peritoneum opened. After incising the pericardium excellent exposure of the heart is obtained. Bleeding from the heart may be controlled by compression of the base of the heart or by plugging the wound with the fingers. When the pericardium is opened a suture is passed through the apex of the heart to steady it; control sutures are then passed near the margins of the wound, and traction of these will control the haemorrhage. This method does not occlude the flow through the coronary and cerebral vessels; it is well tolerated, and a neat approximation of the wound edges can be obtained.

### 234. Pulmonary Complications in Gastric Surgery.

ACCORDING to P. RAZEMON (*Rev. de Chir.*, No. 3, 1926, p. 156), pulmonary complications follow operations on the stomach and duodenum with a gravity and frequency not seen after other surgical procedures. The chief predisposing causes appear to be related to the anaesthetic, the condition of the patient, and the presence of naso-pharyngeal infections. The deficient respiratory movement after operations on the upper abdomen causes pulmonary stasis, and injury to the branches of the vagus nerve is probably of considerable importance. Razemon holds that in cases of ulcer and cancer of the stomach there is always an infective factor present, and during the course of operations the setting free of these bacteria is bound to occur, and they find in the lungs all the conditions favourable for their growth. The bacteria present in the alimentary canal, in cases of resection, may soil the adjacent peritoneum, reach the diaphragm, and then pass to the lungs. To overcome these complications the preoperative disinfection of the site of operation is of great importance, and the careful protection of the peritoneum during the operation. Where the patient has a special susceptibility to these organisms, previously ascertained by their intradermic reaction, preventive inoculation is of great value. In a series of 300 cases where this was performed there was no single case of pulmonary infection. The author adds that the clinical results prove beyond doubt the value of this method.

### 235. Atrophy of Kidney following Chronic Paranephritis.

J. BITSCHAI (*Zentralbl. f. Chir.*, July 10th, 1926, p. 1748) reports the case of a man who had a fall in 1903, followed by lumbar pains, high temperature, and retention of urine. A paravascular abscess formed and was incised. In 1910 he had pain in the right renal region and vomited a considerable quantity of pus, probably due to a perforation of the duodenal wall. In 1911 an abscess burst in the right groin; this healed and broke down again in 1912. Nephrectomy was attempted, but the kidney could neither be felt nor seen in the dense mass of inflammatory tissue occupying the right loin. From 1917 until 1919 there were recurrences of fever and suppuration in the operation scar. The patient was then free from symptoms for four years. In 1924 a paranephritic abscess was incised and the patient was kept under observation in hospital. He had numerous scars below the right twelfth rib, and a large deep discharging sinus in the centre of the recent operation wound. The surrounding skin was deep red and very tender on pressure. The urine was quite normal, and a cystoscopic examination showed no evidence of vesical disease. Chromocystoscopy showed that the flow from the left ureter was normal, but on passing a catheter for a distance of 1.5 cm.

into the right ureter no urine escaped. It was evident that the right kidney was functionless, and for this reason it was useless to attempt pyelography. The wound was enlarged and a very large dense mass of inflammatory tissue was found occupying the right renal region; when opened it was seen that this mass contained an abscess as large as a hen's egg, no trace of kidney tissue being found.

### 236. Treatment of Hypertrophy of the Prostate.

G. DE LARÉ (Arch. des Mal. des Reins, June, 1926, p. 385) discusses the surgical treatment of enlargement of the prostate based on 542 cases submitted to operation. He finds from necropsy specimens that there are in all cases certain perirethral glands which vary in size but which are separated from the prostate itself by the sphincter. When the prostate is hypertrophied this group also becomes enlarged, and post-operative recurrence is probably due to the presence of these glands left behind at the original operation. With regard to the etiology of this disease he believes there is a definite hereditary tendency. In one case the father and son both came to operation at the same time. Operative treatment should be early, and thus destruction of the renal function is prevented. An operation is indicated in the presence of definite symptoms where the patient is unable to micturate spontaneously, and where there is residual urine. At this stage the condition is local and confined to the prostate. As a routine the operation is performed under local anaesthesia and in one stage, a two-stage operation being rarely required. Where there is much residual urine and the renal function is impaired the patient's condition may be considerably improved by the catheter being left in position. In the 542 cases there were 45 deaths, two patients aged 66 being both cured. LARÉ adds that if the general condition is good advanced age is no contraindication to operation. The bladder function is not always completely restored after operation where there has been considerable distension and damage to the muscle beforehand.

### 237. Torsion of the Hydatid of Morgagni.

A. MOUCHET (Bull. et Mém. Soc. Nat. de Chir., June 5th, 1926, p. 555) records two cases of subacute orchitis occurring in boys due to torsion of the sessile hydatid of Morgagni. Twenty-one cases of this condition have been recorded. The patients were about 14 years of age and complained of severe pain in the scrotum. Examination of the scrotum showed none of the signs of inflammation, but palpation revealed a hard mass at the upper pole of the epididymis, which was acutely painful. The spermatic cord and inguinal canal were free from pain on pressure. Transillumination revealed a dark shadow corresponding to the painful swelling. The condition was diagnosed correctly, and at operation the hydatid was found discoloured and swollen and twisted twice on its axis. The pedicle was ligatured and the tumour removed. Convalescence in both cases was uneventful. Mouchet adds that the diagnosis in these cases is simple if the condition is borne in mind. The investigation of translucency shows the position of the tumour and the subacute onset with absence of temperature, and the local signs should enable a correct diagnosis to be made prior to operation.

## Therapeutics.

### 238. Medicinal Treatment of Heart Failure.

E. E. CORNWALL (Med. Journ. and Record, June 16th, 1926, p. 816) observes that the treatment of cardiac failure consists in reducing the work of the heart and improving its nutrition by inducing rest, removing sources of toxæmia, and regulating diet and exercise. Drugs which improve cardiac action may be divided into those which act directly on heart muscle, increasing its contractility and tonicity, and those which improve cardiac action by stimulation of other organs; the former are heart stimulants, the latter heart regulators. Some cases of heart failure require increase of contractility, while others demand the removal of an arrhythmia or stimulation of the regulating nervous mechanism. Digitalis appears to act in two ways—directly on the myocardium, and indirectly by stimulation of the pneumogastric. It increases the excitability and depresses the myocardial conductivity, while indirectly the vagal stimulation depresses myocardial functions generally. It is disputed whether it exercises direct action in increasing contractility and tonicity. Digitalis appears to be a heart regulator rather than a stimulant. By producing partial heart-block or notably delayed conduction, it frees the ventricles by removing auricular fibrillation and flutter. When the rhythm is regular it slows the heart-beat and allows more complete filling of the ventricles and improvement of the coronary circulation. When there is intrinsic disease the ventricles cannot respond, and digitalis

increases the cardiac dilatation (Vaguez). Its specific use appears to be limited to cases of auricular fibrillation and flutter. The action of digitalis seems to be dominated by its vagus effects. Strophanthus appears to be a direct stimulant of the heart muscle, and thus differing from digitalis in this. It increases excitability and depresses conductivity, like digitalis; it does not stimulate the vagus. Cornwall adds that in uncompensated valvular disease, and in dilatation, strophanthus is usually better than digitalis. Quinidine is a heart regulator which is often useful in auricular fibrillation, but there are serious drawbacks to its general use. Atropine blocks the vagus, but its usefulness is limited. Strychnine appears to be a heart regulator through the nerve centres, and increases the secretion or effectiveness of adrenaline. It is particularly useful in cases of low blood pressure. Caffeine is diuretic, but there is no proof that it increases myocardial contractions. It stimulates respiration and the higher cerebral centres, as well as the pneumogastric and sympathetic system. In large doses it may cause mental confusion, so it should be used with caution. Adrenaline is a vaso-constrictor, but its utility in heart failure is less than might be anticipated. Trinitrin and amyl nitrite are vaso-dilators, relieving dangerous or distressing symptoms due to local arterio-sclerosis, and lowering blood pressure in sudden emergencies; they are contra-indicated when blood pressure is low. Calcium is a heart stimulant in cases of calcium deficiency. Morphine is a heart regulator through its sedative action on the nervous system; it is very useful in pulmonary oedema. With digitalis or strophanthus it may relieve dyspnoea; when arterio-dilators fail in angina pectoris morphine must be used, as also in the prolonged distress of progressive heart failure.

### 239. The Therapeutic Action of Ephedrine.

L. POLLAK and W. ROBITSCHER (Wien. klin. Woch., June 24th, 1926, p. 753) have used ephedrine, an alkaloid obtained from the root and stem of *Ephedra vulgaris Helvetica*, in a large number of cases. Although this plant has been a popular remedy in China and Russia for many centuries, the alkaloid was not isolated until 1887, and its use in scientific medicine is still more recent. The chemical composition of ephedrine resembles that of adrenaline, except that the former has no hydroxyl group and the side chain contains a second methyl radicle. Its physiological action resembles that of adrenaline: it raises the blood pressure, and is a mydriatic. Ephedrine reduces the blood sugar content. Applied to the skin its action differs from that of adrenaline, as it has a stimulant effect. It would appear that, in addition to its adrenaline-like action on the end-organs of the sympathetic system, it has a more direct effect on unstriated muscle fibres. A further important distinction is that the effects of ephedrine are more persistent than those of adrenaline, especially in regard to rise of blood pressure. Solutions of ephedrine may be sterilized without destruction of the alkaloid, which is much more stable than adrenaline on exposure to light or heat. Ephedrine is said to be much less toxic than adrenaline, and may be given by the mouth without any diminution of its activity. It has a definite effect on the blood pressure when given in ordinary doses. Hitherto ephedrine has been seldom employed in internal medicine, but the authors have found it of value in circulatory failure after operation and also as an efficient substitute for adrenaline in bronchial asthma. Sialograms of the stomach taken after a barium meal showed that 20 drops of a 10 per cent. solution produced a powerful peristaltic wave in thirty seconds. In some cases palpitation, tremors, and profuse sweating have occurred after internal administration of 0.1 gram of ephedrine in apparently healthy patients.

From the administration of ephedrine than after adrenaline. It is indicated in neurotic patients who have unstable vaso-motor systems; in such cases 20 drops of the 10 per cent. solution will terminate an hysterical attack; many of these patients react well to comparatively small doses of ephedrine.

### 240. Serum Treatment of Anthrax.

S. S. SABOLOTNYI (Centralbl. f. Bakt., July 6th, 1926, p. 53) has collected a small number of cases of anthrax treated with specific serum. He divides them into two groups. The first group contains 27 patients suffering from local anthrax; of these, 3, on account of their mildness, were not given serum, the remainder were all treated with serum and all recovered. The second group contains 7 patients suffering from generalized anthrax with positive blood cultures. Three were not given serum; these all died. Of the remaining 4, which were treated with serum, only one died. The author adds that the serum should be given as early as possible in the disease. It is best given intravenously in large quantities—100 c.cm. at a time—and should be repeatedly injected till the patient recovers.

## Laryngology and Otology.

### 241. Mastoid Abscess.

P. CARCO (*Arch. Ital. di Otol., Rinol. e Laringol.*, April, 1926, p. 187) defines Bezold's abscess as being an abscess in the uppermost part of the neck, lying deep to the sterno-mastoid and splenius, and associated with osteomyelitis of the mastoid process and pus in the cells of its apex. Citelli's abscess occurs in the same position in the neck and is also associated with osteomyelitis of the mastoid, but does not include pus in the cells of the tip. It is associated, however, with an extradural abscess of the posterior fossa, which may or may not be a perisinus abscess. This abscess lies in close relation to the cerebellum and might be complicated by a meningitis. The extradural abscess is formed first and finds its way into the neck by one of three lines. It may pass along the temporo-occipital suture, it may travel along the canal of an emissary vein causing a thrombus, or it may reach the neck by a track of necrosis of the bone. Two cases are described in which pain behind the mastoid process and a brawny swelling in the neck were the first signs of mastoiditis. In both cases the swelling was found to contain pus and there was an osteomyelitis of the mastoid process. The tip of the mastoid was not affected, but there was an extradural abscess round the lower part of the sigmoid sinus in both cases. In one patient the path of the disease could be followed through the temporo-occipital suture, while in the other there was a thrombosed emissary vein running through a necrosed track with a wedge-shaped sequestrum at its outer end. Both patients recovered after operation.

### 142. Mixed Tumour of the Palate.

I. A. SOUCHET (*Rev. de Laryngol., d'Otol. et de Rhinol.*, July 15th, 1926, p. 462) describes the case of a man, aged 62, who had a large tumour of the palate which presented in both the nasal and buccal cavities and caused very considerable embarrassment to breathing and deglutition. It resembled a peritonsillar abscess in appearance, but there was no acute inflammation and it was quite soft and painless. The diagnosis of mixed tumour of the palate was made and an operation was performed to remove it. This was found to be very difficult as there was no capsule and no definite line of cleavage. Microscopically the portions removed were innocent in character and presented the typical appearance of a mixed tumour. Six months later the patient returned with another large mass in the palate, but this time with induration and infiltration of malignancy. This new growth appeared to be growing very rapidly, was causing marked nasal obstruction and discharge, and giving rise to headaches. A circle of six needles of radium of a total mass of 28 mg. was buried round the tumour for nine hours and the procedure repeated two days later. There was a considerable amount of reactionary inflammation followed by necrosis and discharge of pus from the needle holes. The final result was a complete disappearance of the neoplasm. The author considers that these tumours are absolutely benign so long as they remain encapsulated, but when the capsule degenerates and the growth becomes extracapsular the tumour takes on the characters of extreme malignancy.

### 243. The Labyrinthine Reflexes of Position.

V. TANTURRI (*Il Morgagni*, February 7th, 1926, p. 161) reports that reflex tone persists after destruction of the canalicular system, but is lost when the otolith apparatus is also destroyed. The otoliths consist of two on each side—the lapillae in the maculae of the utricles, and the sagittae in the maculae of the saccules. The excitation of the macula is greatest when the otolith is hanging from the macula and is lying horizontally. Hence the reflex of tone is maximal and minimal in two positions of the head which are 180 degrees apart, and in plantigrades is greatest when the head is hanging down. It is thought that the red nucleus presides over these reflexes entirely in the case of the neck muscles, but only partly in the case of the muscles of the trunk and extremities. When the body and head are in a position of repose the stimulus of the sagitta of one side is compensated by the contrary stimulus of the lapilla of the other side and the tonic mechanism is placed at rest. Animals with laterally placed eyes have a particular position of the eyes for every position of the head, and this phenomenon is governed by the reflexes of which the otoliths are the exciting agent. Thus it has been shown that each utricle controls the tonic innervation of the homolateral rectus superior and the heterolateral rectus inferior, and each saccule controls that of the homolateral superior and the heterolateral inferior oblique. The tone of the external and internal recti appears to be controlled by the semicircular canal system, and more especially by the external canals.

548 D

### 214. Phenomena of the Sympathetic System in Rhinology.

E. HALPHEN (*Arch. Internat. de Laryngol., Otol.-Rhinol. et Br.-Oesoph.*, March and April, 1926, pp. 255 and 407) describes certain disturbances in equilibrium of the trigemino-sympathetic systems occurring in the nose. The patients exhibit spasmodic rhinorrhoea, colds, headaches; and retrobulbar neuritis, and the condition is usually originated by some nasal abnormality such as pressure between the septum and the turbinates, spurs on the septum, rarefaction of air in the sinuses, or by infection which may be in the nasal or accessory cavities. The sphenopalatine ganglion is easily affected by inflammation of the deeper and more posterior part of the nose, owing to its close proximity. The secretory symptoms are those of acute colds and spasmodic rhinorrhoea, where a healthy person is suddenly overwhelmed by nasal obstruction and very profuse watery discharge. The equilibrium of such a nose may be upset by the passage from a cold to a warm room. The symptoms end as rapidly as they begin. Treatment is applied to the turbinates, septal spur, or sinus, and the cautery may be enough to give a lasting cure, but sometimes when the nasal condition is cured asthmatic symptoms begin. In some cases pain is experienced to such an extent that acute sinusitis is very closely simulated. Female subjects of the condition are prone to dysmenorrhoea, and it has been observed that ozaena begins as a rule in girls just after puberty. The author treats such cases by injection of the sphenopalatine ganglion. The ganglion may be dissected out. The opening of a closed sinus often causes marked improvement.

## Obstetrics and Gynaecology.

### 245. Magnesium Sulphate in Eclampsia.

E. M. LAZARD, J. C. IRWIN, and J. VRUWINK (*Amer. Journ. Obstet. and Gynecol.*, July, 1926, p. 104), from a collective report of 142 cases of eclampsia treated by intravenous injections of magnesium sulphate, conclude that the development of convulsions can be prevented or controlled after their onset. All toxæmias of pregnancy resulting in convulsions, or in which treatment was directed towards their prevention (pre-eclamptic toxæmias), were included in the series, which showed a mortality of 9 per cent. under this form of treatment, the true nephritic type having the greatest mortality. Pre-eclamptic cases with a blood pressure over 150 were given 20 c.cm. of a 10 per cent. solution of magnesium sulphate intravenously, and this was repeated if no reduction in the blood pressure occurred. In eclamptic cases a similar procedure was adopted as soon as possible after the occurrence of the first convulsion, being repeated every hour until the convulsions were controlled or if the blood pressure continued to rise. In comatose, or semicomatose conditions with delirium, and a falling blood pressure, 20 grains of chloral hydrate and 40 grains of sodium bromide were given per rectum, and preparations were made for delivery as soon as the patient became sufficiently quiet. Such accompanying eliminating measures as phlebotomy, gastric lavage, colonic flushings, and the administration of glucose and soda were found to be of doubtful benefit, and in one or two cases apparently harmful. The authors therefore depend entirely on the intravenous magnesium sulphate treatment, and conclude that intervention should be limited merely to assisting labour, while Caesarean section is contraindicated except in the presence of definite obstetrical indications.

### 246. Simultaneous Intra- and Extrauterine Pregnancy.

E. NOVAK (*Surg., Gynecol. and Obstet.*, July, 1926, p. 26) has collected from the literature thirty-two cases of combined simultaneous intrauterine and extrauterine pregnancy from 1913 to the present day, including two personal cases. These, added to the 244 collected by Neugebauer from 1708 to 1913, brings the total up to 276. Clinically two chief groups are encountered. In the early cases, representing the great majority, the clinical picture is commonly that of ruptured tubal pregnancy, while the uterine gestation is not recognized until operation or later. Occasionally, however, it is the uterine gestation which is recognized in the early months, the extrauterine pregnancy not causing severe symptoms until later. Cases which are first seen in a late stage of pregnancy have commonly been regarded as cases of normal pregnancy until the occurrence of extrauterine symptoms. Finally, in some cases both pregnancies have advanced to term, and in nine of these both children have been delivered alive. The treatment varies with each case. In early cases laparotomy is required. In the later cases the same plan

# EPITOME OF CURRENT MEDICAL LITERATURE.

may be advisable, although at times towards the end of pregnancy expectant treatment is justifiable until the onset of labour, when operative removal of both foetuses is indicated.

247. H. STIGLHAUER (Wien. Klin. Woch., June 3rd, 1926, p. 656) records the case of a woman, aged 35, in whom laparotomy was performed for tubal gestation, when the right tube was removed and the uterus was found to be of the size and shape corresponding to that of pregnancy at the beginning of the third month. The patient made a good recovery from the operation, and in the ninth month of pregnancy gave birth to a normal child after fourteen hours' labour. In most of the cases of simultaneous intra- and extra-uterine pregnancy, comparatively few of which have been recorded, intrauterine pregnancy has ended in abortion after death of the extrauterine ovum. In the cases reported by Kellerscheidt and Wittauer the intrauterine pregnancy lasted longer than the extrauterine, which was not recorded. In Strauss's case death from septicaemia occurred a few weeks after operation. In Weibel's case, on the other hand, abortion came first, and was followed a few days later by laparotomy for extrauterine pregnancy. Interruption of intrauterine pregnancy is the rule in these cases of double pregnancy, which, according to Weibel, occurs in one out of 149 cases of extrauterine gestation. The frequency of abortion, for which infection of the haematocoele is responsible, gives rise to a mortality of 35 per cent. The continuation of intrauterine pregnancy and the spontaneous birth of a normal child, as in the present case, is, the author adds, a remarkable event.

248. Drainage Treatment of Infected Abortions. G. SCHWARTZ (Zentrabl. f. Gynäk., May 8th, 1926, p. 1251) discusses the treatment of uncomplicated cases of fever following abortion and adopts Winter's distinction between (1) active treatment, whereby the uterus is emptied as soon as infection is diagnosed; (2) conservative treatment, which leaves the emptying of the uterus to nature while aiding by administration of stimulants to the uterine muscle; and (3) expectant treatment, which begins as in the conservative method but empties the uterus operatively when the pyrexia has disappeared. Statistical comparisons of the relative efficacy of these therapeutic methods in a given case when the infection passes the bounds of the uterus and renders the case "complicated," while the degree of resistance; the larger the patient's power of resistance, and it has been found that cases receive their cases at an earlier stage are less likely to be abortifacient, when active treatment is strongly in favour of conservative treatment, and it has been found that one of its disadvantages—the longer average duration of treatment as compared with that of active therapy—is considerably diminished by the adoption of gauze drainage through the cervix. After disinfection of the vagina a narrow strip of gauze is introduced within the internal os—after the mechanical dilatation if necessary. This strip is changed each day until the disappearance of blood, the pro- complete as shown by the disappearance of blood, the pro- discharge, the uterus gradually becoming smaller, the pro- gressive closure of the cervix, and the cleanliness of the uterine secretion. Details are given of twenty-four uncomplicated febrile cases of abortion and of eighteen cases of febrile abortion, which were treated by gauze drainage alone. There were no deaths, and the average duration of treatment was twenty days and fifteen days respectively; about one-third of the patients in the vagina or cervix. The gauze haemolytic streptococci in five or six successive days and the placental remnants were spontaneously expelled after the second or third change as a rule. Severe haemorrhage was rarely encountered and yielded to introduction of a wider piece of gauze, whereby firmer uterine contraction was induced.

249. Pregnancy and Cancer of the Large Intestine. H. KATZ and F. KASPAR (Arch. f. Gynäk., March 25th, 1926, p. 250) find that the association of cancer of the colon or rectum with pregnancy is somewhat less frequent than that of cancer of the uterus. They report eighteen cases from Vienna clinics, of which fourteen were of rectal carcinoma, all of which were operated on by the sacral route only. Although in certain cases the growth increases more rapidly during pregnancy when the tumour has occurred together with pregnancy. One patient with a non-metastatic cancer of the large intestine had several pregnancies separated by many years of good health. The authors add that in inoperable cases colostomy does not seem to increase the

risk of infection during labour and may bring about a very striking improvement in the patient's general condition. Prognosis would be better if examination of the rectum and colon were made in all pregnant patients reporting intestinal pain or chronic obstruction.

250. Prevention of Maternal Morbidity. H. JACOBS (Med. Journ. of Australia, May 29th, 1926, p. 533; and June 5th, 1926, p. 627) discusses the question whether pregnancy and parturition can be considered physiologically normal. He concludes that they are so in most cases, but that many are not. The term "maternal morbidity" may be applied in either a general or in a restricted sense. The former covers abnormalities occurring immediately or at some remote period after labour, while the latter is applicable only to abnormal conditions immediately following labour. The etiology of this morbidity may be classified broadly as—infection, traumatism, toxæmia. Discussing the incidence of maternal morbidity amongst civilized nations the author estimates that for every two hundred children born one mother dies. Puerperal infection is held to be responsible to the extent of 30 per cent., and he gives a lengthy list of the organisms and increase the virulence of the primary infection. He especially deprecates frequent vaginal examinations, and recommends the use of aseptic and often abdominal palpation. He condemns the use of forceps and often unnecessary application of forceps and emphasizes the value of pre-natal care in the treatment of abnormalities, thereby avoiding the dangers attending craniotomy or crushing operations. The control of bleeding is the primary indication in placenta praevia, and podalic version the best method; in eclampsia the elimination of toxins is of chief importance. Jacobs is opposed to the performance of Caesarean section in either of these conditions, or in cases of pelvic contraction without due consideration. On the other hand, pubiotomy has proved valuable and safe in competent hands in selected cases of obstruction. Discussing the treatment of puerperal infections, he advises against local treatment.

251. Sterility associated with Habitual Amenorrhoea. I. C. RUBIN (Amer. Journ. Obstet. and Gynecol., July, 1926, p. 76) has found amenorrhoea associated with sterility 74 times in 1,450 consecutive cases. There is some evidence that mild x-ray doses are useful therapeutically, and Rubin has treated twelve patients thus with nine subsequent pregnancies (75 per cent.), whereas in untreated cases pregnancy occurs in only about 5.5 per cent. Of these nine patients only one aborted, the remaining eight continuing to full term and giving birth to normal children. Irradiation of the ovaries resulted in the restoration of the menses in eleven out of the twelve cases, and it was found that irradiation of the hypophysis area and of the thyroid appeared to be helpful, while tubal insufflation and endocrine therapy were additional aids to the x-ray treatment. In eight of the nine successful cases the ovaries were found to be definitely enlarged before treatment, and Rubin considers that careful examination should assist in selecting cases suitable for ovarian radiation. In the absence of ovarian enlargement, irradiation of the hypophyseal area or of the thyroid may be the better course and should certainly precede ovarian irradiation. The x-ray dose recommended for amenorrhoea is 5 to 10 per cent. of the skin erythema dose, but much depends upon the age of the patient, the apparatus used, and the dose needed to produce a skin erythema.

## Pathology.

252. The Rationale of the Bile Solubility of the Pneumococcus. E. E. ATKIN (Brit. Journ. Exper. Path., August, 1926, p. 167) has tried to discover why some strains of pneumococci dissolve readily and completely in ox bile, while others only so slowly and incompletely; some even fail to dissolve at all. He believes he has detected an absolute correlation between the autolysin content of the solvent action of bile and its susceptibility to the solvent action of bile. Cultures were grown on horse-serum agar slopes of a reaction of pH 7.5 and 7.8, and the amount of autolysin that occurred between the second and fourth days was observed. In many instances the growth almost disappeared within this time. Autolysin occurred best at pH 7.5 in the case of Types 1 and 2, and at pH 7.5 in the case of Type 3. The bile solubility of the same strains was tested by suspending an overnight growth in horse-serum agar in saline and mixing with a 1 in 1,000 and a 1 in 2,000 solution of sodium desoxycholate. It was found that Types 1 and 2 were more readily soluble when taken from a growth on medium of pH 7.8 than on medium of pH 7.5; with Type 3 548 E

the converse held good. From these experiments it would appear that the cocci which contain the most autolysin are the most readily soluble in bile salts. It was also noticed that after four or five days on a serum agar plate secondary papillae sometimes formed from the already autolysing colonies. The organisms in these papillae did not undergo autolysis; even after incubation for a fortnight or so they kept their form and remained Gram-positive; moreover, they were insoluble in bile salts. If they were transplanted on to a fresh serum agar slope they again formed autolysin and again became susceptible to bile salts. The author therefore concludes that the bile solubility of the pneumococcus is due to an acceleration of the normal autolytic process, and that no solution of the organisms occurs except in the presence of autolysin. The function of the bile is to assist the autolytic enzymes secreted by the bacteria in much the same way as in the human body it assists the digestive enzymes of the alimentary canal.

#### 253. The Preparation of Antimeningococcus Serums.

In order to produce a polyvalent serum it has been customary to inject horses with large numbers of representative strains. A. WADSWORTH and M. B. KIRKBRIDE (*Amer. Journ. Hygiene*, July, 1926, p. 507) state, however, that this method defeats its own ends; instead of obtaining a high-titre polyvalent serum the serum is found to be deficient in both these properties. In their experiments they prepared serums by injecting horses with 4, 6, 20, and 60 strains of meningococci, and tested their potency by the agglutination test; they give reasons for considering this the most valuable test. Both as regards titre and polyvalency the 6-strain serum was superior to the others; it was followed closely by the 4-strain serum. The average titre—tested against 26 strains of meningococci—of the 20-strain serum was little more than a third of that given by the 6-strain serum, while that of the 60-strain was less than a quarter. They conclude, therefore, that the best method of producing a potent anti-bacterial serum for the meningococcus is to employ about six representative strains. In 13 cases of cerebro-spinal meningitis in patients over 1 year old and treated by the 60-strain serum the mortality was 15.3 per cent., and in 68 cases treated by the 6-strain serum it was 11.7 per cent. In infants under 1 year the mortality in 32 cases treated by polyvalent serum was 43.7 per cent. It was noticed that some cases entirely failed to react to the serum; on the other hand, a number which reacted favourably developed fatal secondary complications or infections. The authors add that the mortality in the group over 1 year of age is remarkably low, and compares favourably with Flexner and Jobling's figures.

#### 254. Calcification and Ossification of Goitre.

E. CAPORALI (*Arch. Ital. di Chir.*, June, 1926, p. 673), who records a case in a woman aged 39, states that, according to some authorities, calcification is fairly frequent in goitre. In 194 goitres at the Basle surgical clinic Hunziker and Pfister found calcification in 67, or 34.5 per cent., and in 16 of these there was more or less extensive ossification, while Sehart found calcification in 14 out of 28 goitres. In Caporali's experience, however, the frequency of calcification in goitre is much less, as in 84 cases of goitre operated on at the Pisa surgical clinic only two showed any calcification. According to Nivet about 50 per cent. of the calcification is caused by calcium phosphate, 9 per cent. by calcium carbonate, and 40 per cent. by organic matter. In Caporali's cases, on the other hand, the figures were very different, the calcium phosphate being 18.54 per cent., calcium carbonate 80.95 per cent., and non-identified organic matter 0.5 per cent. The ossification must be regarded as a metaplasia of the connective tissue of the goitre. In Caporali's cases the diagnosis of calcification was made by x-ray examination, and zones of ossification were found on section after successful removal of the goitre.

#### 255. Incidence of Pneumococcus Types in Pneumonias of Children.

RUTH E. WESTLUND (*Journ. Infec. Dis.*, June, 1926, p. 514) has compared the types of pneumococci in the pneumonias of childhood with those found in children suffering from other respiratory diseases. Since sputum was difficult to obtain, she used throat swabs. Her figures relate to the types of pneumococci found in the throats of children suffering from pneumonia and other diseases; in several instances, therefore, more than one type of organism was recovered from the same patient. One series of 69 cases of lobar pneumonia and another of 34 cases of bronchopneumonia were examined; the children ranged from three weeks to eleven years in age. In the first series pneumococci were recovered from the nasopharynx in 60.8 per cent., in the latter series in 52.6 per cent. of cases. These organisms were typed by the usual methods. The distribution amongst the types was similar in both series: Type IV formed about

three-quarters; Type II came next, being 19.7 per cent. in the lobar pneumonia and 12.5 per cent. in the bronchopneumonia series; Types I and III were present in only small numbers. The author notes that the difference between the distribution of types in children and in adults is very striking; in adults the fixed types are present in large numbers in lobar pneumonia, while in children the fixed types constitute only a quarter of the total number of strains. The great predominance of Type IV strains in this series and the close similarity in the proportions found in the two types of pneumonia suggest that the throat swab method yields results that are not comparable with those given by sputum examination. This is further borne out by the finding that the distribution of pneumococci in the throats of children suffering from other respiratory diseases and from non-respiratory diseases is very much the same as that in children suffering from pneumonia.

#### 256. The Rous Sarcoma.

P. C. FLU of Leyden (*Centralbl. f. Bakt.*, August 5th, 1926, p. 332) has repeated a number of Gye's experiments on the factors influencing the infectivity of the Rous sarcoma for chickens, and differs from Gye's conclusion with regard to the disinfecting power of chloroform. Using suspensions of staphylococci, *B. coli*, and *V. cholerae*, Flu found that in order to sterilize them 0.3 c.cm. of chloroform acting at 37°C. for three hours was required for every 10 c.cm.; less than this proved unreliable. The same amount of chloroform also sufficed to destroy the infectivity of a Rous sarcoma filtrate. Smaller quantities, such as 0.1 c.cm., sometimes proved ineffective, for though the injection of 1 c.cm. of chloroform-treated filtrate did not produce a tumour, the injection of 2, 4, or 8 c.cm. frequently did. When Flu repeated Gye's experiments on the activation of the virus by a chloroform-treated sand filtrate of a Rous sarcoma he succeeded only in those instances in which insufficient chloroform had been added to destroy the virus completely. He failed uniformly to obtain activation by chloroform-treated filtrates which by themselves were non-infective in a dose of 4 or 8 c.cm. In other words, the "specific factor" when sterilized completely was no longer active. Flu finds that cultures from tumours can be replaced by extracts of normal organs. Thus a sand filtrate of a Rous sarcoma that had been treated with chloroform to render it non-infective gave rise to a tumour when it was mixed not only with cultures from other tumours but with an extract of normal fowl liver or kidney. That is to say, if Gye's hypothesis is correct, these normal tissues must have contained the virus. Flu failed to infect mice with a cell-free filtrate of cultures of mouse sarcoma, and he brings forward evidence to show that the Rous sarcoma is not a malignant tumour at all but a proliferative inflammatory condition. His experiments failed to substantiate the conception of a virus present in all tumours and of a secondary factor specific to each; in his opinion Gye's results can be more simply explained by Bail's aggressin theory.

#### 257. Serological Diagnosis of Neuro-Syphilis.

H. F. WATSON (*Quart. Journ. Med.*, July, 1926, p. 431) records the results of a critical analysis of certain laboratory methods applied to the cerebro-spinal fluid in the serological diagnosis of neuro-syphilis with a view to establishing their correct diagnostic value. The procedures investigated included the Wassermann test of the serum and the cerebro-spinal fluid, the colloidal gold test, the foam test, various globulin estimations, and the enumeration of cells, including in most cases the differential count. The personal history and clinical condition of each patient were also investigated. Of the 350 cases examined 119 were syphilitic and the remainder were classed as non-syphilitic as they gave no history or clinical evidence and the Wassermann tests were negative. In the clinically syphilitic cases the Wassermann test was positive with cerebro-spinal fluid in 95.65 per cent. and with serum in 94.78 per cent.; 85.84 per cent. were positive to the colloidal gold test. Of the globulin tests the Pandy, mercuric chloride, and sulpho-salicylic acid gave approximately 95 per cent. positive results; the Noguchi 86 per cent.; and the Ross-Jones, Nonne-Apelt, and Kaplan 71 per cent. The colloidal gold, globulin, and foam tests frequently gave positive results in such non-syphilitic conditions as encephalitis lethargica, disseminated sclerosis, acute rheumatism, mumps, and late influenza, thus rendering them unreliable in diagnosis. From this investigation Watson concludes that the Wassermann test is of most diagnostic value and affords the highest percentage of positive results in known syphilitic cases, while the colloidal gold test gives a much lower percentage. In syphilitic conditions the Pandy, sulpho-salicylic acid, and mercuric chloride globulin tests approximate the Wassermann test in percentage of positive results. In the syphilitic conditions of the central nervous system the cell enumeration was never lower than 10 per c.mm.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 258. Accidents Due to Lumbar Puncture.

J. C. MELINDRO (*Arch. de med., chir. y exp.*, June 5th, 1926, p. 435), who records an illustrative case in a young woman aged 18, states that the frequency of meningism following lumbar puncture varies considerably with different observers. In the natives of the Congo this sequel was never observed (Blanchard and Laligret). In Nonne's series of 3,000 cases of lumbar puncture it was noted in 6 per cent. Perkel's estimate was 37.8 per cent., whereas Melindro himself observed meningism in only 5 out of 224 cases of lumbar puncture, or in 2.2 per cent. The differences in these statistics depend on the amount of fluid removed, the position of the patient, the size of the trocar employed, and the duration of rest enforced after lumbar puncture. Melindro uses a trocar with a diameter of 1.5 mm., with the patient in the lateral decubitus. After 6 to 8 c.cm. of cerebro-spinal fluid have been withdrawn the patient is made to lie down with his head low for twenty-four hours. Perkel, on the other hand, performs lumbar puncture when the patients are sitting up, and allows them to get up two or three hours after removal of the fluid. The treatment employed by Melindro for the meningism following lumbar puncture consists in epidural injection of normal saline solution in doses of 20 to 30 c.cm. Good results were obtained in all cases, though the following day the patients who had hitherto been afebrile had a "salt fever" of 101.2° F. In addition to meningism there are cases on record of lumbar puncture being followed by death (which is a very rare occurrence and not always attributable to the puncture), paralysis of the cranial nerves, psychical disturbance (Kaiser), fatal meningitis (Sonnenschein), and aggravation of the primary disease, as in a case of epilepsy observed by Melindro in which eight attacks occurred after lumbar puncture, whereas previously there had only been one a week.

### 259. The Dick Test in Scarlet Fever.

R. DEBRÉ, M. LAMY, and H. BONNET (*Ann. de méd.*, May, 1926, p. 457) have performed the Dick test on 1,154 children, aged from a few days to 15 years; 736, or 63.8 per cent., were negative; 391, or 33.8 per cent., were positive; and 29, or 2.5 per cent., gave a pseudo-reaction. As a general rule positive results were least frequent in the first year (25 per cent.), but became more frequent from 1 to 3 (47 per cent.), and then became rarer with increase in age until they fell to 17 per cent. at the age of 15 years. One of the authors made 800 tests in a reformatory in the United States and obtained positive reactions in only 15 per cent., whereas the usual percentage of positive reactions in such communities in the United States is 70. An explanation for this was found in the fact that scarlet fever was endemic in the institution (40 cases a year on the average), so that many children became immunized. Moreover, 50 per cent. of the children had *Streptococcus haemolyticus* in their nasopharynx. Of 233 adults tested in France 205 were negative, and only 26, or about 11 per cent., positive; while of 1,700 aged from 15 to 20 attending secondary schools in America examined by one of the authors 490, or about 28 per cent., were positive. Of 38 patients examined at the onset of scarlet fever only 11 gave a positive reaction, which was usually ill marked, 26 a negative, and 1 a pseudo-reaction. Zingher, on the other hand, found that the reaction was almost always (99 per cent.) positive in the first three days of the disease. The present authors' experience agrees with that of the Dicks, who found the reaction positive in only 50 per cent. of the cases at the onset of scarlet fever. In convalescence only one of Debré's cases was positive. Like American observers, the present authors found that the serum of Dick-negative subjects blanched the scarlet fever rash in the 21 cases studied; 13 patients whose Dick test was positive were used as controls, and with none of them was blanching of the rash obtained. The authors also found that there was an absolute parallelism between neutralization of the toxin by the serum *in vitro* and blanching of the rash.

259. N. P. SHERWOOD and L. BAUMGARTNER (*Journ. Immunol.*, 1926, ii, p. 323) have performed a series of Dick tests on university students, and have compared them with the agglutination reactions to the streptococcus of scarlatina. Contrary to the early findings, they obtained 25 per cent. of positive Dick tests in 44 persons giving a history of scarlet fever nine or more years previously, while of 132 persons

with no history of scarlet fever only 33.3 per cent. were positive. It is noteworthy that over half of the former group of persons gave weak positive reactions. As regards the agglutination test 14.5 per cent. of Dick-positives contained agglutinins in their serum, compared with 25.5 per cent. of Dick-negatives. Among those giving no history of scarlet fever 11.3 per cent. of Dick-positives contained agglutinins, as against 26.1 per cent. of Dick-negatives. These results would appear to show that in adult life the interpretation of the Dick reaction is very difficult, especially in the absence of a definite history of scarlet fever. Previous results have given a high percentage of negative Dick reactors among those who have suffered from the disease; these results are not confirmed by the present authors. So far as the agglutination reaction is concerned the present work shows that this is more likely to be positive in Dick-negative persons and in persons giving a history of scarlet fever.

### 261. Influenzal Endocarditis.

E. H. OPPENHEIMER (*Bull. Johns Hopkins Hosp.*, May, 1926, p. 372) records a fatal case of endocarditis in a man, aged 28. The protracted course, cardiac disease, splenomegaly, haemorrhagic nephritis, petechial eruption, fever, and clubbing of the digits, with an onset suggestive of a cerebral accident, was characteristic of *Streptococcus viridans* infection, while anatomically the type of vegetation on the chronically diseased and thickened valves, the widespread petechiae, infarcts, and embolic nephritis fitted in detail into the same picture. *B. influenzae*, however, was obtained from blood cultures on the day before death and *post mortem* in smears from vegetation on the heart valves. A review of the literature shows that *S. viridans* is responsible for 95 per cent. of the cases of subacute bacterial endocarditis, while Pfeiffer's bacillus is the etiological factor in most of the remaining 5 per cent. Cases of *B. influenzae* endocarditis have been reported by Libman and Horder (*JOURNAL*, 1920, ii, p. 301).

## Surgery.

### 262. Urological Causes of Abdominal Pain.

J. D. BARNEY (*Boston Med. and Surg. Journ.*, July 15th, 1926, p. 111) remarks that abdominal symptoms originating in the kidney or ureter may resemble those originating in almost any abdominal organ, and that a correct diagnosis may only be reached after a complete urological examination with uroterograms and pyelograms. The difficulty in differential diagnosis is increased by the fact that the pain may simulate that associated with the appendix, gall bladder, gastrointestinal tract, or female pelvic organs, even in the presence of a normal urine and negative x-ray examination, since such data in themselves do not necessarily exclude the kidney and ureter from consideration. The uroterogram may be quite as important as the pyelogram in detecting stricture of the ureter—a condition which, especially in women, may be a cause of abdominal pain. Kinks of the ureter usually occur in the upper half, causing faulty drainage of the renal pelvis, followed by infection, dilatation, and adhesions, and proceeding possibly to complete destruction of the kidney. Aberrant renal vessels may interfere with drainage and cause hydronephrosis, and malpositions of the kidney which show little or nothing on physical examination may yet produce severe abdominal symptoms. Horseshoe kidney may give rise to abdominal pain resembling that of appendicitis, and bifurcations of the pelvis or ureter are among other congenital abnormalities complicating diagnosis.

### 263. Chronic Duodenal Ileus.

AS C. C. HIGGINS (*Arch. of Surg.*, July, 1926, p. 1) points out, the relation between acute dilatation of the stomach and duodenal obstruction by compression of the duodenum by the root of the mesentery has caused considerable discussion in late years. Chronic duodenal ileus is not a rare condition, and there are many cases which are not diagnosed. Various conditions may predispose to this condition, and four chief groups may be considered: congenital abnormalities, the formation of adhesions, factors favouring compression of the duodenum, and factors favouring a pelvic position of the intestines. This condition is found more frequently in females, and usually in middle age. On account of the severe headache associated with the condition a diagnosis of migraine is usually made. In all cases of severe headache associated with vomiting a careful examination of the

duodenum should be made. Where the dilatation is insufficient to produce duodenal stasis relief should be brought about by non-operative measures. If the dilatation is marked and stasis with antipe should be performed, and excellent results should not be performed, as the stasis in the duodenum is not relieved and a vicious circle is established. A careful x-ray examination must be made before operation, and the correct diagnosis be thus established. Higgins maintains that dilatation of the duodenum is a clinical entity, and that a characteristic picture is present in most of the cases.

#### 251. Treatment of Recurrent Laryngeal Nerve Paralysis.

C. H. FRAZIER (*Surg., Gynecol., and Obstet.*, August, 1926, p. 134) describes an operation for restoring the function of the recurrent laryngeal nerve after injury, especially after thyroidectomy. Injury of this nerve implies paralysis of the intrinsic muscles of the larynx; the cord hangs in a flaccid state and narrows the lumen of the larynx by approaching and finally reaching the mid-line. In this state dyspnoea becomes acute. Gradually the cord loses its tonus, the glottic chink is again widened, and "total" or "complete" paralysis supervenes. Anastomosis of the proximal portion of one nerve to the peripheral portion of another is an accepted procedure, and has been adopted by Frazier in traumatic recurrent laryngeal palsy. For this purpose the descendens hypoglossi is selected for anatomical and physiological reasons. Lying close to the recurrent laryngeal, it is easily accessible and of sufficient length to afford transportation without tension; physiologically, it is motor in function and supplies muscles the action of which is correlated with those of the larynx. Anastomosis with the phrenic nerve has also been successfully accomplished. In operating, the first step consists in isolating and identifying the stump of the recurrent laryngeal, the dissection beginning at the point of entrance of the nerve into the larynx—that is, at the inferior cornu of the thyroid cartilage. When found the nerve is traced downwards until the point of severance or constriction appears. Occasionally the injuring agent may be only scar tissue, the nerve itself being undamaged. The descendens hypoglossi as it courses along the anterior carotid sheath is next isolated, cut above the ansa hypoglossi, and an anastomosis made with the previously isolated recurrent laryngeal. The operation is performed for the relief of dyspnoea, the discarding of the tracheal cannula, and the restoration of normal phonation. Conditions adverse to success are complete atrophy and fibrosis of the muscle of the cord, immobilization of the cricoarytenoid joint, tracheal stenosis, and absence of a segment of the nerve. Frazier considers this anastomosis with the descendens noni branch of the hypoglossal nerve or with the phrenic a safe procedure, and thinks that improvement can be expected in 60 per cent. of cases.

#### 265. Fibro-epithelial Tumours of the Renal Pelvis.

S. PERLMANN (*Dent. Zeit. f. Chir.*, July, 1926, p. 378) states that fibro-epitheliomatous tumours of the renal pelvis are among the rarer forms of renal tumour. Their frequency varies, according to different observers, from 2 in 68 (Israel) to 10 in 283 (Mayo Clinic); Mock collected 95 cases in 1913, 102 were reported by Spiess in 1915, and 68 by Hryntschach in 1920, since when Perlmann has collected 43 from the literature, including four which came under his own observation. A study of all these cases shows that fibro-epitheliomata of the renal pelvis are more frequent in men (62 per cent.) than in women (38 per cent.). They occur most often between the ages of 50 and 60, but Thomas has reported a case at 3½ years. Most writers state that both sides are affected with equal frequency, but in Perlmann's experience the tumour is most frequent on the left. Bilateral localization is rare. Three groups of fibro-epithelioma of the renal pelvis may be distinguished—namely, typical fibro-epithelioma, atypical fibro-epithelioma, and papillary carcinoma, of which 29 of Perlmann's 43 cases were examples. The most prominent clinical symptom is haematuria, which was present in from 74 to 84 per cent. of the cases, as the first and very frequently the only symptom of the disease. Pain, which sometimes accompanies the haematuria, may be colicky, or of a dull persistent character. Pain as an isolated symptom without haematuria is rare, being noted in only three of Perlmann's cases. Occasionally the presence of a tumour is the first thing which makes the patient seek medical advice. The urine contains red corpuscles, numerous epithelial cells, and sometimes fragments of tumour. Besides the ordinary methods of investigation pyelography should always be performed, as it often enables a correct diagnosis to be made before operation. As regards operative treatment, nephrectomy-ureterectomy is said to be the method of choice. Secondary tumours arising in the bladder must be subjected to endovesical coagulation.

## Therapeutics.

#### 266. The Bactericidal Action of Silver Chloride.

B. PFAB (*Med. Klin.*, June 18th, 1926, p. 962) refers to the long-continued use by Saxl of silver chloride in cases of gastric ulcer with very good results. The salt was obtained in colloid form by precipitation from silver nitrate in the presence of organic colloids which prevent the precipitation of inorganic colloids, and remains in permanent suspension. Saxl believes that the beneficial action of silver chloride is enhanced by the addition of atropin, which relieves pain. Pfab has confirmed Saxl's clinical observations by experiments and finds that silver chloride is powerfully bactericidal and has also analgesic properties, due, perhaps, to its power of stimulating the growth of granulation tissue. There was rapid improvement in varicose ulcers when dressed with the colloid solution in dilutions of 1 to 10 per cent. or with ointments containing 2 to 15 per cent. of the colloid substance. A 4 per cent. solution of colloid silver chloride was usually employed; this had no irritating effect on mucous membranes, skin, or wounds. Saxl administered silver chloride internally to more than 100 patients, without causing argyria, except in one case in which large doses of sodium bicarbonate were given after food. Cultures of *B. coli* and *B. typhosus* on agar plates treated with solutions of colloid silver chloride varying from 1 to 10 per cent. were sterile at the end of twenty-four hours, while the control culture showed a free growth. Experimental staphylococcal abscesses in guinea-pigs healed rapidly when treated with the colloid silver chloride ointment. It was found that a dilution of 1 in 800 destroyed bacteria, while in a dilution of 1 in 3,000,000 all bacterial growth was inhibited.

#### 267. Intensive Iodine Medication in the Treatment of Chronic Rheumatism.

M. J. THIROLOIX, Mme BRACH-GILLOT, and M. LELOUP (*Bull. et Mem. Soc. Méd. des Hôp. de Paris*, June 24th, 1926, p. 1033) describe the treatment of 193 cases of chronic arthritis by administration of methyl or benzyl iodide combined with hexamethylene tetramine, usually by intravenous injection, and in large doses, two or three times a day. They found that this treatment caused all varieties of articular lesions due to chronic rheumatism to disappear. They included as rheumatism a non-infective arthritis associated with endocrine deficiency, mainly of the thyroid and ovary, and a second type which was of infective origin. In all affected cases the basal metabolic rate was constantly lowered; it was rare to find a chronic rheumatic woman with a morphologically normal thyroid, and the iodine was believed to act by raising this rate to normal and stimulating the endocrine glands primarily affected. Conditions benefited or cured included rheumatic gout, acute gout, chronic arthritis following serum sickness, "glandular rheumatism" in a patient the subject of ovarian trouble, severe arthritis with wasting, tuberculous and syphilitic arthritis, and chronic rheumatism following congenital deformities, such as dislocation of hip, and sacralization of the fifth lumbar vertebra. Treatment of pregnant women with arthritis was continued to the eighth month without detriment.

#### 268. Vaccine Treatment of Asthma.

A. PONDMAN (*Nederl. Tijdschr. v. Geneesk.*, May 29th, 1926, p. 2237), from observations on 400 cases of asthma, comes to the following conclusions. No definite micro-organism can be regarded as the cause of asthma; tubercle bacilli, even when special search was made for them, could seldom be found. The fact that almost the same result was obtained whatever the vaccine employed indicates that the method is an example of bacterial protein-therapy rather than a specific vaccine treatment, and that successful results must be ascribed to a desensitizing process. In complicated cases the result of the treatment is usually slight, and at most only some improvement can be obtained. In young patients vaccine treatment is followed by a remarkable improvement in the general condition, accompanied by an amelioration of the asthmatic process. The number of patients who completely recovered was small, but many of them were living under unfavourable circumstances as regards hygiene and nourishment.

#### 269. Specific Treatment of Plague.

C. BIFULCO (*Stadium*, May 20th, 1926, p. 169) quotes Montefusco's statement that the favourable results obtained by various observers with antiplague serum were undoubtedly due to the mildness of the prevailing epidemic rather than to the efficacy of the serum, its method of preparation, or the route by which it was injected. In two epidemics of plague in 1904 and 1921 the mortality among the patients at the Contugno Hospital, Naples, not treated with serum was only 11.5 per cent., a figure which is much lower than that

obtained in India with antiplague serum, either by the German mission (50 per cent.) or by the Russian mission (40 per cent.). Wiguna and Jassenil had a mortality of 33 per cent. among their cases of plague treated by serum at Pondichy. The failure of antiplague serum has been attributed by several to deficiency of bactericidal action and almost complete absence of plagne antitoxin. According to Biffalo, Montefusco is to be credited with having introduced an anti-plague vaccine which he has employed in very severe cases with successful results. A daily dose of 5 c.cm. of the vaccine is given subcutaneously as long as there is no improvement or fall of temperature. In many cases a considerable fall of temperature and improvement in the general condition occur after the first injection. Treatment of plague by intrabubonic injection of d'Hérelle's bacteriophage has only been given to patients who would probably have recovered without this treatment.

## Disease in Childhood.

### 270. Typhoid Fever in Infants.

W. WESTON, jun., and S. X. RADNITT. (*Arch. of Ped.*, March, 1926, p. 180) review the literature and state that during the period 1915 to 1925 there were a hundred cases of typhoid fever in the Children's Hospital at Philadelphia. Five of the children were less than 1 year old, and two of the five had meningitis due to *E. typhosus*, one apparently a primary infection. The rarity of typhoid fever at this age is probably due to the smaller chance of exposure and not to any lesser degree of susceptibility. Eight deaths occurred in the whole series, four being in patients in the first year of life. The younger the child the more frequent were the complications of typhoid fever, and death was due to these in most instances. Otitis and furunculosis were the complications most frequently observed by the authors. Haemorrhage and perforation are, they state, uncommon in infants, none having occurred in their series, but relapses are more frequent in early life than later. Four of the authors' patients had relapses, one having two relapses eight days apart.

### 271. Flat-foot in Infants and Children.

P. LEWIN (*Amer. Journ. Dis. Child.*, May, 1926, p. 704) holds that the various periods at which feet should be inspected are: at birth, 6 months, 1 year, 2 years, 3 years, 4 years, and at adolescence. Any condition causing weakened musculature may cause flat-foot. There is a definite type of weak, pronated, or flat foot that appears with adolescence—in long slender rapidly growing feet, especially in girls. Obesity causes flat-foot in two ways: by the strain of an excessive load and by glandular disbalance in such conditions as

a or infantile paralysis.

The author explains that the deformity consists of an eversion of the foot with abduction of the forepart of the foot at the tarso-metatarsal articulations. There is a downward and inward rotation of the medial bones of the mid-tarsal region—namely, the scaphoid, internal and middle cuneiform bones. The upper border of the astragalus is tilted medially, carrying the inner border lower than the outer. There is gaping of the bones on the inner border of the foot—the scaphoid, os calcis, astragalus, and internal cuneiform. There is compression of the bones on the outer border of the foot—the cuboid, os calcis, and astragalus. The structures on the outer side of the joint are shortened and generally strengthened, while those on the inner side are stretched and weakened. The indications for treatment are to teach proper walking, to increase the power of the supporting structures, to increase the local circulation, to support the weakened structures, to produce supination, and to correct associated pathological conditions, such as knock-knee, bow-legs, etc. The methods of meeting these indications are prescribing proper foot-gear, exercises, massage, contrast foot-baths, felt pads, plaster-of-Paris casts, and operation. The child should be taught to walk with the feet parallel or toeing in slightly. It should come down on its heels, tilt its weight to the outer borders of the feet, and come up on the toes with a spring. Well fitted laced boots should be worn. The most important movement is from the back of the heel to the middle of the big toe joint, which should be opposite the point at which the shank joins the ball of the sole. Next, the foot must grasp the heel. The author advocates the Thomas heel, for which four measurements are necessary: (1) from the tip of the os calcis to the anterior border of the scaphoid tubercle; (2) from the tip of the os calcis to a perpendicular line dropped from the anterior border of the external malleolus; (3) the inner border height of heel, which should be  $\frac{1}{8}$  to  $\frac{1}{4}$  of an inch higher than (4) the outer border or normal height of heel. He describes the eleven exercises he has found most

valuable. Support for the longitudinal arch is obtained by means of felt pads. These afford a resilient support and thereby increase the spring of the gait. They are inserted directly into the shoes and held by means of a special glue and tacks. Plaster-of-Paris is necessary in some cases, preliminary forcible manipulation under anaesthesia being indicated for rigid flat-foot. Resection of the peroneal tendons, lengthening of the Achilles tendon, tendon transplantation, osteotomy of the os calcis or other bones is occasionally indicated. The single outside calliper and T-strap of Jones and the lever sole of Calot are sometimes of value.

### 272. The Fate of Infants Born before Term.

L. SALOMONSEN (*Tidsskrift f. d. Norske Lægeforening*, May 1st, 1926, p. 429) has traced the infants who were born before term at the 8th Department of the Ullevaal Hospital in Oslo. There were 64 such infants, whose weight at birth was under 5½ lb. Of these 64, as many as 11 died within a month of birth. Within three years of birth 25, or 39 per cent., had died. Of the surviving 39, who were observed for a period of more than a year, 8, or 21 per cent., showed evidence of mental deficiency. Of the 15 who were observed for a period of more than three years as many as 5 were mentally abnormal. The calculation that 39 per cent. of the total had died within three years of birth was an underestimate, as several of the infants under observation were not yet 3 years old. But it is rather the mental inferiority than the proportion of actual survivals among the infants born before term that Salomonsen considers significant, and he gives details of cases showing how mentally inferior much of this material is. He considers that Ylppö, dealing with more than 650 infants weighing less than 5½ lb., had proved in 1919 that more than 7 per cent. of the surviving infants were mentally abnormal, and that this observation has gone far to upset the orthodox teaching that it does not matter much if a child is born before term provided it survives the first few critical months.

### 273. Acrodynia.

A. E. VIPOND (*Brit. Journ. Child. Dis.*, April-June, 1926, p. 127) describes the cardinal symptoms of this disease, which occurs chiefly in infants between the ages of 8 to 18 months, as follows: The onset is associated with nasal catarrh, and the child becomes restless and cross. A definite rash appears on the body, often of the nature of an erythema; there is occasionally a papular or even a pustular eruption. The hands and feet are cold, and the skin presents a bluish red appearance, the same condition affecting the tips of the nose, ears, and eyelids; in some cases bullae and superficial gangrene develop. The locomotor system is involved, the hands and feet being thrown about, but not for any useful purpose. The sensory system is much disturbed. There is intense pain in the arms and legs; cutaneous sensibility is lost or much lessened. All the superficial lymphatic glands are enlarged, especially in the axillae and inguinal regions. There is a rapid loss of weight, the reflexes are difficult to obtain, and the child suffers from mental irritability. The usual duration of the disease is from four to six months, but Vipond has considerably shortened it by injection of an autogenous vaccine prepared from a diplococcus which he has constantly found in the enlarged lymphatic glands.

## Obstetrics and Gynaecology.

### 274. Puerperal Mortality.

R. L. DE NORMANDIE (*Boston Med. and Surg. Journ.*, May 27th, 1926, p. 963) discusses the question of maternal deaths from haemorrhage, septicaemia, and puerperal albuminuria with convulsions. Vaginal haemorrhage during pregnancy is abnormal and should be investigated; its importance is not, however, generally recognized. Admission to hospital is advisable, as severe haemorrhage may follow examination. The question of Caesarean section must be decided quickly; if abdominal palpation and rectal examination indicate abdominal delivery, vaginal examination is inadmissible and very dangerous. The more nearly the patient has approached term the greater the probability that Caesarean section will be required: Abdominal rigidity and tenderness usually indicate laparotomy. If a preliminary vaginal examination is decided upon the most rigorous aseptic technique must be employed; too frequently the preparation of the patient is insufficient. Haemorrhage from a ruptured varix can only be discovered by the preliminary introduction of a vaginal speculum; the vaginal fornices should then be palpated, avoiding the cervix. If the presenting part is felt immediately, placenta praevia is not the cause of the haemorrhage, but if there is the characteristic boggy feel the uterus must be emptied. The cervix should not be dilated manually but by a large bag, or a careful external version

should be performed. Caesarean section is not always required; the patient must be uninfected and in good condition, and the child alive and apparently healthy. When the bleeding is due to a separated placenta the author recommends Caesarean section, even if the child be dead, unless the os is fully dilated. Post-partum haemorrhage can be largely obviated by correct technique and the use of pituitrin after delivery. If called to a case of severe haemorrhage, in the absence of sufficient assistance the obstetrician should pack the vagina lightly with sterile gauze. In puerperal septicaemia the majority of cases are infected from outside; very few patients are properly prepared according to modern surgical standards. The bowel must be emptied and the vulva and surrounding area shaved and sterilized. The author recommends preparation with ether and iodine or picric acid or mercurochrome; unless the soap and water scrubbing is very carefully done there is danger of soiled water flowing into the vagina. Vaginal examinations should be made as seldom as possible, and a strict surgical technique observed. In cases of puerperal albuminuria and convulsions a careful medical supervision will practically eliminate eclampsia. All patients should be watched for symptoms of toxæmia. The blood pressure should be frequently estimated, as a slight rise, with or without albuminuria, must be regarded as the first sign of toxæmia; the patient should be seen at least once a week. Continued hypopæsis requires rest in bed and eliminative treatment. Nausea, headache, and vertigo may indicate induction of labour. The author adds that the only way to lessen puerperal mortality from this cause is for every patient to have complete medical supervision during pregnancy.

#### 275. Pituitrin in Obstetrics.

M. L. MÜLLER (*Nederl. Tijdschr. v. Geneesk.*, March 6th, p. 945) since 1916 has employed pituitrin in 97 out of 732 labours, of which 70 occurred in primiparae and 27 in multiparae. Of the primiparae who were given injections of pituitrin for uterine inertia only three were under 23 years of age, twenty-six were between 23 and 29, and the remaining forty-one were above 29, eleven being over 35. In 24 cases labour lasted more than thirty-six hours, the longest period being five days. In 42 cases a single injection of half a cubic centimetre was given, in 24 cases two injections, and in 4 cases three injections. Not a single child was born within a quarter of an hour of the first injection, and only 3 within half an hour; 43 were born between half an hour and two hours later, and 24 between two and four hours, 10 of the last being forceps cases. None of the 70 children died and all the mothers survived. In multiparae secondary inertia was the chief indication for injection of pituitrin, and in only a few cases was the drug required for primary inertia. In 25 cases a single injection was sufficient, and only two patients required two injections. After the first injection twelve women were delivered within a quarter of an hour, sometimes after a single pain, and seven within half an hour. Five were delivered within one hour, and in only three did labour last longer than an hour after the injection. None of the children showed asphyxia, and labour was spontaneous in every case. Haemorrhage occurred in 28 of the 97 cases, but only in cases of primary or secondary inertia in which it would have occurred without pituitrin.

#### 276. Dystocia from Double-headed Foetus.

G. V. ZUR-MÜHLEN (*Zentralbl. f. Gynäk.*, June 5th, 1926, p. 1514) relates the case of a 2-para, aged 28, who, from the large size of her abdomen during the seventh month and at the commencement of labour, and from the signs present at the latter occasion, was thought to have twin gestation. A head was to be felt through an os admitting one finger, and a larger round hard body was palpable above the pubis abdominally. Twenty-four hours after commencement of labour the os was almost fully dilated, the waters had not broken, and the head was fixed with the sagittal suture transverse. After several attempts had failed the head was drawn down by forceps and the chin brought over the perineum, the foetus being at this stage alive; the impossibility of completely delivering after bringing down an arm led to suspicion of foetal malformation, but on account of the large size of the head complete pelvic exploration was impossible. At a Caesarean section the second head was removed, the foetus having died in the meantime, and the remaining parts, together with the placenta, were removed through the vagina. The uterus was removed and the patient recovered after a febrile puerperium. Decapitation of the first head and removal of the first-coming arm appeared to be contraindicated by the risk of rupturing the uterus; also the foetus at that stage was alive. Preservation of the uterus seemed to be forbidden by the danger of infection; at the termination of the vaginal portion of delivery the episiotomy wound had become a complete rupture of the perineum.

## Pathology.

#### 277. Intrapericardial Pressure as a Cause of Death.

C. S. WILLIAMSON and H. N. ETS (*Arch. Intern. Med.*, August 15th, 1926, p. 205) record results of an experimental study of the mode of action of therapeutic puncture in pericardial effusions. Notes of four cases of sudden death in uncomplicated pericardial effusion are given, and of fifty-four previously reported fatal cases of pericarditis with effusion in which puncture was not performed it is suggested that thirteen might have been benefited by the procedure. It is generally believed that circulation ceases when the intrapericardial pressure equals that in the cavæ, but at present we have no clinical means of measuring these pressures. The authors' experiments on dogs to determine the relations between arterial, venous, and intrapericardial pressures in the presence of artificial pericardial effusions showed that a gradual rise in the intrapericardial pressure invariably resulted in raising the venous and lowering the arterial pressure, and that as the intrapericardial pressure approximated that which obtained in the vena cava, that is, the point at which the circulation stops, the rise in the venous and the drop in the arterial pressures became more noticeable. Clinically a steady fall in blood pressure, and especially a sudden increase in the rate of fall, indicate an increasing intrapericardial pressure and a near approach to the critical point calling for therapeutic puncture for its relief. In most instances the tracings showed that an increase in pressure sufficient to stop the heart was associated with recovery, even if only temporary. The authors conclude from these experiments that it is the intrapericardial pressure which is the real criterion of danger, and that this is proportionate to the rapidity with which the effusion develops and not to its extent.

#### 278. Functional Pathology of Nephritis.

E. B. MAYNS (*Quart. Journ. Med.*, April, 1926, p. 273) endeavours to correlate the symptoms of nephritis and to find an explanation of their causes consistent with our present knowledge of the physiology of the kidney. The chief symptoms of hydraemic or chronic parenchymatous nephritis appear to be due to the lowering of the colloid osmotic pressure of the plasma, probably from loss of protein through damaged glomeruli, such pressure being unable to resist sufficiently the capillary blood pressure, thus allowing excess of fluid to be forced through the capillary endothelium into the tissues, with resulting oedema and tendency to blood concentration, as shown by an absolute increase in the globulin content of the plasma, and also by an increased corpuscle-plasma ratio. In azotaemic or chronic interstitial nephritis the tubule function of concentration is impaired, and in severe cases the total molecular concentration of the urine may never exceed that of the plasma, with the resulting failure of the tubule cells to overcome osmotic resistance. While many of the glomeruli retain their permeability it is impossible to determine whether a sufficient number remain in action to produce the normal amount of filtrate. Although the urea is always concentrated, the urine of advanced azotaemic nephritis never contains as much chloride as the plasma, and the suggested explanation is based on the idea of an equilibrium at an osmotic resistance which the tubule cells cannot overcome, and at which normal reabsorption can no longer proceed and undesired substances commence to diffuse back through the tubule cells.

#### 279. Determination of the Specific Gravity of a Small Quantity of Urine.

J. KIRKPATRICK and D. H. KLING (*Journ. Amer. Med. Assoc.*, August 14th, 1926, p. 487) describe a method of determining the specific gravity of urine when only a few drops are obtainable, as for example after ureteral catheterization. In a urometer jar carbon tetrachloride and xylene are placed in the proportion of 1 to 3.5 and mixed thoroughly by stirring, a useful stirring rod being an ordinary applicator stick. The resulting specific gravity will be 1.020 at a temperature of 77° F. For each degree fall in temperature there is added to the urometer reading 0.0005 degree and vice versa; that is, for each 2 degrees rise in temperature, the standard urometer scale is to be read 0.001 degree lower than it appears. A drop of urine is let fall into this mixture. If the drop sinks to the bottom its specific gravity must be higher than the mixture and lower if it floats. The specific gravity of the mixture is increased in the former case by adding carbon tetrachloride, and decreased in the latter by adding xylene, slowly and with adequate stirring, until the drop of urine neither rises nor falls. The reading on the urometer scale will then be equivalent to the specific gravity of the urine after the necessary corrections for temperature differences have been made. Correct results are said to depend entirely on adequate stirring of the mixture and on temperature corrections.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

250.

### Diabetic Xanthomata.

A. CHAUFFARD and P. BRODIN (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, June 24th, 1926, p. 1003) report the case of a fat man, with a large appetite normally, who in 1920 developed increased hunger and thirst, further obesity, and loss of strength. In 1921 xanthomata appeared on the limbs; they were few and discrete at first, but later increased in number and became confluent. In 1923 a diagnosis of diabetes of syphilitic origin was made, the Wassermann reaction being positive, and two courses of novarsenobillon cured the xanthomata. When the authors saw him shortly afterwards the xanthomata had recurred on the limbs, the blood sugar figure was 1.75 grams, cholesterolin 9.72 grams, and the total fat 82 grams. After six weeks' insulin treatment the xanthomata had vanished and the blood showed glucose 1.25 grams, cholesterolin 2.88, and total fat 13.20. In July, 1925, the xanthomata reappeared and the lipaemia was 56 grams, reappearance of the skin lesions being associated with increase in the lipaemia, and cholesterolin; treatment with insulin caused the disappearance of the nodules and lowering of the two latter. Throughout this period there was no glycosuria and only very slight raising of the blood sugar level, whereas there was considerable variation in the lipaemia level. A certain amount of dieting was associated with some but not all courses of insulin. The authors deduce that treatment by insulin should be associated with a diet low in fats and carbohydrates but fairly rich in albuminous foods. When the blood fat was between 40 to 50 grams and the cholesterolin between 5 to 6 grams the xanthomata appeared; below 30 grams and 5 grams respectively the nodules disappeared, suggesting the presence of a threshold for lipid deposition in the tissues. They consider that insulin has a beneficial action on the fat in circulation and also on that deposited in the tissues, when given in large doses (30 to 50 units); also that the internal secretion of the pancreas, like the external, has both amylolytic and lipolytic actions.

251.

### Subacute Endocarditis.

A. KROPVELD, JUN. (*Nederl. Tijdschr. v. Geneesk.*, July 3rd, 1926, p. 25), who records an illustrative case, states that subacute endocarditis (endocarditis lenta), of which the clinical picture was first described by Osler, was shown by Schottmüller to be due to *Streptococcus viridans*. The majority of cases run a fatal course. Kropveld's patient was a woman, aged 42, who for the previous two years had been treated by four otologists for relapsing otitis. There was no history of articular rheumatism. Finally, a diagnosis of mastoiditis was made, but nothing abnormal was found on operation. The temperature was irregular and there was marked anaemia. Although examination of the heart revealed nothing beyond an occasional extrasystole, *Streptococcus viridans* was cultivated from the blood, and rapid recovery followed the injection of an autogenous vaccine. When soon five months after discharge from hospital the patient had resumed her work as a teacher and showed no symptoms, except a slight impairment of hearing.

282.

W. L. BIERING (*Journ. Amer. Med. Assoc.*, August 14th, 1926, p. 464) states that this condition is a distinct disease entity, and must be distinguished from endocarditis accompanying acute or subacute rheumatism, acute ulcerative or acute malignant endocarditis, and endocarditis occurring as a terminal event in chronic disease; the term subacute should be applied to cases lasting three months or longer. A pre-existing valve lesion is essential for the production of this form of endocarditis, the chronically injured valve affording a predisposing site for the new infection; since this is almost exclusively a disease affecting adults, the valves on the left side of the heart are chiefly involved. The commonest cause of the valvular lesion is acute rheumatism; syphilis and scarlet fever are less frequent, while arterio-sclerosis is rare. Since the war trench fever, gonorrhoea, and influenza have assumed a causative importance. The infection is caused mainly by two micro-organisms—the *Streptococcus viridans* and *D. influenzae*. The causal microbe always has the common characteristic of low virulence, with no tendency to pyogenic effects, and the blood is often free from bacteria for long periods. The course often extends over one or two years, and presents a distinctive clinical picture. The onset is insidious, and is characterized by lassitude, vague pains, headache, vertigo, and cough; a diagnosis of tuberculosis,

mild sepsis, subacute rheumatism, malaria, or typhoid is often considered. The main clinical symptoms may be divided into an early period, expressive of a low grade infection, and characterized by fever, anaemia, exhaustion, and enlarged spleen, and a later period, when symptoms due to endocardial changes arise, such as petechiae, tender cutaneous nodes, clubbing of the fingers, vascular embolism, purpura, and renal phenomena; cardiac symptoms are singularly rare. The patient usually succumbs to the progressive anaemia and exhaustion; pulmonary and visceral congestion with uraemia and coma are the terminal complications. The prognosis is grave, very few cases of recovery having been reported. A successful or specific form of treatment has yet to be discovered; vaccine therapy has been tried, but with little success. Blood transfusion, immuno-transfusion, and treatment with a large number of drugs, principally the colloidal metals, have proved of small value. As arsenic is retained for a long period in the serum, and as it inhibits the growth of low-virulent streptococci, intravenous injections of large doses of sodium cacodylate have been administered with some good effect. Biering joins Horder in advocating preventive measures, and emphasizes the need of keeping the vitality at its highest, of promoting immunization in every possible way, and of preventing acute infections.

### 283. Prophylaxis of Varicella with Vesicle Fluid.

R. M. GREENTHAL (*Amer. Journ. Dis. Child.*, June, 1926, p. 851) inoculated 36 persons against varicella with the contents of a fresh vesicle which were expressed from a capillary tube on to the forearm, and forty to fifty incisions were made through the fluid into the epidermis without drawing blood. Successful inoculation was shown by the appearance of a papule between the eighth and thirteenth day at the site of inoculation. The papule rapidly changed into a vesicle and the vesicle into a crust which later dropped off, leaving a scar resembling that left by small-pox vaccination. Of the 36 inoculations 19 were successful, 16 were failures, and one patient left hospital before the eighth day. No cases of varicella developed among those who had been inoculated either successfully or unsuccessfully. It was impossible to be sure that these patients had never had varicella before, because the history is often unreliable. Greenthal considers, however, that the results are sufficiently encouraging to justify further trial of the method.

285.

### Diagnosis of Thyroid Syndromes.

M. LABBÉ (*Presse Méd.*, August 14th, 1926, p. 1025) remarks that besides typical cases of myxoedema and Basedow's disease there are many atypical cases in which diagnosis is very difficult. At the beginning of a tuberculous exacerbation the palpitation, tachycardia, emaciation, slight enlargement of the thyroid, and slight temperature so simulate the commencement of an exophthalmic goitre that diagnosis is often very uncertain, and must depend on physiological tests and biological reactions. In myxoedema the reaction to treatment with either fresh or dried thyroid gland is often decisive. Quinine and adrenaline have also been used, and Labbé favours the use of the latter, the symptoms produced by it in Basedow's disease being acceleration of the pulse, inversion of the oculo-cardiac reflex, and an increase in the hyperglycaemic reaction; these are fairly constant. In all physiological tests the chief characteristic is the measure of basal metabolism, there always being an increase of organic oxidation in cases of Basedow's disease, and a diminution in myxoedema, mental conditions, and in lesions of the alimentary tract. In cases of obesity and emaciation Labbé asserts that it is always advisable to test the activity of the thyroid as this gland governs nutrition; he insists that physiological tests, and chiefly that of basal metabolism, afford the only means of diagnosis in diseases of the thyroid.

285.

### Exophthalmic Goitre.

B. J. SANGER (*Arch. Intern. Med.*, May 15th, 1926, p. 627) gives an account of 50 cases of exophthalmic goitre treated with x-rays and kept under observation for several years, clinical examinations and estimations of the basal metabolic rate being made at frequent intervals. The average number of x-ray treatments required was ten, with a maximum of twenty-seven and a minimum of three. Improvement in symptoms was usually rapid, the patients feeling distinctly better and less toxic. A tendency to gain in weight, often before there had been any fall in the basal metabolism, and disappearance of nervousness and sleeplessness, were among the early signs of improvement; in early cases palpitation

and tachycardia quickly disappeared, though they were more persistent in cases of longer standing. Of his 50 patients 41 became and remained cured, and of the remainder 3 were improved, 4 were operated upon, and 2 were lost sight of. The treatment rarely caused any discomfort, and the majority were treated as ambulatory patients with advice to rest as much as possible and to take a high caloric diet, only those with severe myocardial symptoms being ordered complete rest. Sanger concludes that the treatment is safe and satisfactory, and offers a high percentage of cures.

#### 285. Antityphoid Inoculation by Mouth.

A. LUMIÈRE (*Paris Méd.*, June 12th, 1926, p. 562) states that the causes of the occasional failure of antityphoid inoculation by mouth may be divided into two groups—namely, (1) causes common to all methods of treatment, and (2) those peculiar to the special technique employed. Whatever method is used, the specificity, doses, virulence, and individual reaction all help to modify the degree of efficacy of the immunization, which must not always be regarded as certain and absolute. For this reason antityphoid vaccination, whatever route is followed, should not be regarded as rendering unnecessary all the hygienic precautions used by non-immunized persons. In the case of inoculation by the gastro-intestinal tract it is not possible to be certain always of the entrance of the typhoid and paratyphoid bacilli into the system. In exceptional cases it may happen that the capsules containing the vaccine pass through the intestine without being broken up. This does not occur in persons whose digestive functions are normal, but is only met with in those whose digestion is upset by insufficiency of glandular secretions, exaggerated peristalsis, gastro-intestinal fistula, or any other cause. Apart from other benefits the oral method has the advantage of always being harmless, whereas injections sometimes entail more or less severe complications, being followed by pains, fever, and polymorphous eruptions. Lumière adds that the addition of bile to vaccine taken by the mouth is useless, in view of the fact that the few centigrams of dried bile are extremely slowly diffused through an intestine which normally receives 800 to 1,000 c.c. of bile. Such diluted bile has been shown, moreover, to have no action on the intestinal mucous membrane.

#### 287. Epidemic Encephalitis and Infantile Convulsions.

F. GLASER (*Monatsschr. f. Kinderheilk.*, June, 1926, p. 289) records five cases of epidemic encephalitis associated with convulsions in children between the first and third years of life which he had observed during the outbreak of encephalitis and influenza at Breslau from 1921 to 1923. All showed typical drowsiness and signs of meningeal irritation, and in one case myoclonic movements. Three patients made a complete recovery, and two had more or less severe permanent nervous impairment. Glaser suggests the name of "encephalitis epidemica meningitica seu convulsiva" for these cases, as they represent a group of convulsions of unknown origin. Epidemic encephalitis should therefore be regarded as another cause of infantile convulsions. The cases which Glaser has described form a transition between serous meningitis and epidemic encephalitis, especially in one case where the clinical symptoms suggested tuberculous meningitis or serous meningitis, and the diagnosis of epidemic encephalitis was first established by the examination of the cerebro-spinal fluid.

## Surgery.

#### 288. Bier's Treatment of Sinuses.

H. ECKSTEIN (*Zentralbl. f. Chir.*, July 17th, 1926, p. 1834) has employed Bier's congestion treatment in a number of cases and reports four in which it was successful. The first was in a patient who had a sinus in the abdominal wall after an operation for removal of fat for plastic purposes. A Bier's cup was applied for a quarter of an hour for three or four days, when some gauze appeared in the sinus. A plug of gauze about the size of a walnut was then readily extracted with forceps, and the sinus closed on the following day. The second case was that of a patient who had a sinus in the abdominal wall following an operation for appendicitis one year previously. After several days' treatment with a Bier's cup the end of a very thick ligature appeared. On gentle traction the whole ligature, measuring from 10 to 20 cm., was drawn out, and the sinus immediately closed. In the third case the sinus following an abdominal operation closed after two applications of the cup, although no foreign body was found. In the fourth case also a sinus over the left external malleolus due to a gunshot wound healed after two applications, although no foreign body was discovered. No bad effects followed the treatment, which only occasionally required a little patience.

620 B

#### 289. Scarlet Fever after Surgical Operations.

ACCORDING to B. R. LOWETT (*Journ. Amer. Med. Assoc.*, July 10th, 1925, p. 96), scarlet fever is not an infrequent sequel of operations on the nose and throat. The patient may harbour the organisms in the nose or throat previously, but be able to escape infection until an open wound allows them to invade the tissues in large numbers. The operation may facilitate infection from outside, either from a person suffering from scarlet fever or a carrier of scarlatinal streptococci. Of 43 cases classified as surgical scarlet fever between 1902 and 1926 at the Durand Hospital, Chicago, 20 followed operations, 13 of which were on the nose and throat. Of these 7 were operations for cleft palate, 2 resections of nasal septum, and 4 tonsillectomies. The interval between the operation and the first symptom of scarlet fever was two to four days. All the patients had typical scarlet fever, mostly of the septic type. Complications were unusually numerous. In most of the cleft palate cases there was sloughing of the tissues and imperfect closure of the defect; one patient operated on for cleft palate and hare-lip died. There are numerous examples on record of scarlet fever following tracheotomy, and one case each after removal of a tumour of the jaws and of papilloma of the tongue.

#### 290. Gastro-Jejunal Ulcer.

D. C. BALFOUR (*Annals of Surgery*, August, 1926, p. 271) asserts that recurrence of ulceration may follow any operation for peptic ulcer, including partial gastrectomy, and that the hypertonic type of individual is prone to recurrence of ulceration. The condition is only rarely seen in women, and usually follows operation for duodenal ulcer. In more than half the cases recurrence of symptoms occurred within a year of the primary operation. The treatment, according to Balfour, depends on the conditions found at operation. If the duodenal ulcer is healed the simplest and most rational procedure is to disconnect the anastomosis and excise the gastro-jejunal ulcer. If this is impossible, owing to scarring or other reasons, the simplest procedure is to disconnect the anastomosis, excise the ulcer, and perform partial gastrectomy. The symptomatic results following partial gastrectomy for gastro-jejunal ulcer are said to justify the operation fully. Complete relief of symptoms follows in 85 per cent. of cases, whilst the mortality is only 3 per cent. Balfour maintains that the incidence of this condition, after a properly performed gastro-enterostomy, in well selected cases, is about 2 per cent. When it occurs an immediate secondary operation is necessary.

#### 291. Statistics of Goitre Operations.

G. FIEDLER (*Deut. Zeit. f. Chir.*, August, 1926, p. 82) states that from April, 1896, to April, 1925, operations were performed on 266 patients with goitre in the Magdeburg-Alstadt hospital; 256 were males and 242 females. The right side was principally affected in 72 cases, the left in 63, the middle lobe in 15, and both sides in 115. In 3.3 per cent. there was a well marked retrosternal goitre. In 30 cases in females there were typical symptoms of Graves's disease. The pathological findings were as follows: typical colloid goitre, 192 cases (72.1 per cent.); cystic goitre, 30 cases (12 per cent.); parenchymatous goitre, 34 cases (12.7 per cent.); malignant goitre, 6 cases (2.2 per cent.); vascular goitre, 3 cases (1 per cent.); thyroiditis, 1 case. The ages of the patients ranged from 1 to 80. Most of the male cases occurred between the ages of 15 and 20, and most of the female cases between the second and the fourth decennium, 11.3 per cent. developing during pregnancy or the puerperium. There was an hereditary history of goitre in 7.1 per cent. of the female cases, but there was no history of this kind in the male cases. The total mortality was 14 cases (5.2 per cent.), but of the patients with simple goitre only 3 (1.3 per cent.) died, death being due to air embolism in two cases and to cardiac failure in one case.

#### 292. Wound Complications.

L. K. FERGUSON (*Therapeutic Gazette*, August 15th, 1926, p. 541) has collected a series of 757 clean operation cases which were not primarily infected and required no drainage. Wound complications occurred in 7.9 per cent. and were responsible for a loss of one hospital bed for three-fourths of each year. They arose more frequently after inhalation than after local anaesthesia and in operations lasting more than half an hour, in which latter they were more serious. Wound complications occurred in 11.8 per cent. herniorrhaphies, with infection in 8 per cent.; in 6.2 per cent. gridiron incisions, with infection in 2.2 per cent.; in 47.5 per cent. right rectus incisions, with infection in 27.5 per cent. Serum collections and fat necrosis were noted in 2 per cent. of clean wounds, starting on the fifth to the tenth day, and delaying the patient's recovery by a day or two. Haematomas occurred in 1.3 per cent. and appeared from the second to the fifth day, retarding the patient less than five days. Wound infections occurred

in 4.6 per cent., commencing on the second to the fifth day, with an average consequent delay of 10.8 days. Ferguson concludes that such complications most frequently follow prolonged operation exposure and trauma of the tissues, and in upper right rectus incisions in which it is difficult to humbly effectively the wound edges owing to respiratory movements and changes in posture. Incomplete haemostasis, and the occurrence of dead spaces when incisions are closed under tension, are other factors in the causation of complications. Among preventive measures suggested are: (1) the use of a fresh scalpel after the skin incision, in order to prevent carrying infection to the deeper layers; (2) care in obtaining complete haemostasis, in order to prevent oozing after the wound is closed; (3) making sufficiently large incisions to reduce the damage due to retraction; (4) the application of wound gauze covers as soon as the incision is completed, in order to decrease trauma and exposure; (5) the prevention of dead space by inserting silk worm gut tension sutures; (6) closing the wound with clips to insure good approximation and to avoid puncturing subcutaneous vessels; and (7) the application of light adhesive dressings to immobilize the wound as much as possible.

### 233. Accessory Spleen in Congenital Inguinal Hernia.

H. FINLAY (Nederl. Tijdschr. v. Geneesk., July 24th, 1926, p. 337) reports an example of this condition in an infant. The left testis appeared to be almost twice as large as the right, and of an entirely different shape. The processus vaginalis was found to be open and the testis was present in the hernial sac. The upper part of the epididymis showed a round swelling the size of a bean, of a brownish-blue colour, and covered with peritoneum; this swelling was found to consist of typical spleen tissue. The author has traced only one similar case, that reported by Sneath, in which an accessory spleen stimulating a third testis was connected with the primary spleen by fine cords. Finlay suggests as one explanation of his case that the rudiment of the spleen was situated in the epididymis, before the descent of the testis occurred. A second explanation which appears to him to be more likely is that the rudiment of the spleen became implanted in a fold of peritoneum, which later became the processus vaginalis.

### 234. Traumatic Perforation of the Appendix.

R. GUTZERT (Zentralbl. f. Chir., July 31st, 1926, p. 1943) has collected a number of reports of this unusual injury and describes the case of a boy, aged 14, who was kicked in the appendix region by a horse. The appendix, which lay in the right iliac fossa, was ruptured by flatus or faecal matter forced into the appendix by the kick, the thinner wall of the appendix being the point of least resistance. Faecal extravasation occurred, followed by symptoms of severe peritonitis. The author states that perforation of the appendix may occur in the course of gangrenous appendicitis; by the entry of a pointed or angular foreign body which has passed into the lumen of the appendix; by ulceration of the serous coat of the appendix by a periappendicular abscess; and by traumatic laceration of the appendix in the course of an abdominal injury. In traumatic perforation of the appendix there may be perforation from the serous to the mucous coat, bursting of the appendix wall as the result of compression by the caecum, bursting of the appendix through torsion or kicking, especially when adhesions are present, or laceration of the appendix by fragments of a fractured os innominatum. Gutzert considers that traumatic perforation of the appendix should be clearly distinguished from traumatic appendicitis following a lesion of the mucosa of the appendix, which permits bacterial invasion of the submucous tissues; traumatic perforation is usually due to an injury of the peritoneal coat.

## Therapeutics.

### 235. Treatment of Pneumococcal and Streptococcal Meningitis.

J. A. KOLMER (Arch. Otolaryngol., June, 1926, p. 481) has studied the treatment of artificially induced meningitis in rabbits, rats, and dogs. Ethylhydrocuprein hydrochloride and mercuriochrome were injected intraspinally, intracranially, subdurally, and intravenously without effect, the treated animals dying as quickly as the untreated controls. Gentian violet, acriflavine, and rivanol were next tried and were injected in the same ways, but with the same disappointing results. In the cases of ventricular injection of gentian violet, however, the injected ventricles were found at necropsy to be deeply stained and free from pns, indicating a local bactericidal effect. The same negative results followed the injection of antistreptococcal serum by the above mentioned routes, but slightly better results were obtained by

injection of antibody solution. When, however, this was combined with lavage of the subarachnoid space the results were very good. Lavage alone, with warm saline solutions, from the ventricles to the cisterna magna saved a number of dogs infected with a haemolytic streptococcus and Type I pneumococcus. In some instances lavage of one ventricle was sufficient, but recoveries followed lavage of either one or both, although the latter is a more severe treatment necessitating the trephining of both sides of the head. Kolmer thinks that lavage from the cisterna magna to the lumbar region of the spinal subarachnoid space will probably prove helpful, but it was not found necessary in the treatment of dogs. He believes that continuous drainage from the cisterna magna or lumbar subarachnoid space will still further improve results and furnish a method of value in the treatment of septic meningitis in human beings.

### 236.

### Treatment of Neuro-syphilis.

H. A. BUNKER, jun. (Amer. Med. Journ., June, 1926, p. 1815), observes that it is often difficult, and occasionally impossible, to make a differential diagnosis between the various types of and parenchymatous types of symptoms are present clinical examinations of the spinal fluid may not be of value. From the standpoint of treatment he holds, however, that this distinction is of much less importance than the necessity of controlling therapeutic measures with repeated examinations of the spinal fluid. While the findings in the cerebro-spinal fluid remain positive in spite of the disappearance of clinical symptoms, it cannot be concluded that a satisfactory therapeutic conclusion has been reached, and the particular line of treatment employed should therefore be changed or intensified. He suggests that malarial treatment is especially valuable in such intractable cases because, unlike specific methods, it does not involve a long period of time and may prevent the onset of paresis.

### 237. Combined Oral Administration of Insulin and Saponin.

F. LASCH and S. BRÜGEL (Wien. klin. Woch., July 8th, 1926, p. 817) have been investigating the action of saponins on the alimentary tract; it has previously been shown that these increase the absorptive capacity of the gut for certain drugs, such as digitoxin and strophanthin, when given in combination with them. The authors have now tested their effect when given with other drugs, such as calcium and grape sugar, and in both cases there was increased absorption; they report also their results with insulin. With insulin doses of 10-20 units only they combined pure white saponin (Merck) 0.5 gram in saline solution; the two substances were swallowed with a little water. Neither of these preparations when given alone had had any appreciable effect on the blood sugar, but in combination the result was as follows. Half an hour to one hour later the blood sugar began to fall; it reached its lowest point in about three hours and returned to the normal in about seven hours. In one acute case of diabetes the blood sugar fell from 0.2 gram per cent. to 0.13 per cent. in four hours. There were no toxic symptoms in any cases. The authors think that this method will make possible the ideal dosage in insulin treatment—namely, the giving of small quantities at frequent intervals.

### 238. Causes of Failure in Cardiac Medication.

R. GIRAUX (Paris Méd., July 3rd, 1926, p. 28) remarks that although the remarkable action of digitalis and of ouabain in various forms of cardiac failure is well known, there are certain cases in which these drugs have only a transient, or even a negative, effect on the progress of the disease. The failure may be due to some cardiac defect, the improper prescription of digitalis and ouabain, derangements of the alimentary tract, pleural or peritoneal effusions, or to anaemia which blocks the action of cardiac tonics. Other causes of failure are acute cardiac rheumatism, myocarditis, secondary endocarditis in chronic heart disease, adhesive pericarditis, cardiac failure in scoliosis and other thoracic deformities, pulmonary arterio-sclerosis, chronic pulmonary lesions, and cardiac failure with regular pulse. In addition to these causes there may be sudden irrecoverable heart failure, a special form well described by Vaquez. These considerations must be remembered in making a prognosis. Treatment may be ineffective or badly tolerated; complications occur and the patient dies, usually within a year of the onset of symptoms of heart failure, without any evidence of modification or temporary arrest of the progress of the disease: the heart's action remains rapid but regular, especially in cases of mitral or aortic valvular disease. In the former arrhythmia usually occurs sooner or later, and digitalis administered every month gives relief. It is quite otherwise when the rhythm is regular. In certain cases of aortic valvular disease the extreme hypertrophy of the left

ventricle interferes with the normal action of the right ventricle. The result is a dilatation with hypertrophy of the right auricle; usually the rhythm remains regular, in spite of the progress of the disease. In these cases the most desirable event would be the occurrence of complete arrhythmia, which might then be relieved by treatment. The action of digitalis on the sinus is so feeble that it cannot reduce the pulse rate, but Giroux finds that its powerful effect on conductivity is most evident in complete arrhythmia. This is also true of ouabain, which acts so powerfully and quickly in sudden cardiac dilatation, especially of the left ventricle. Surgical treatment of pericardial and pleural adhesions offer some prospect of relief which therapeutic measures cannot give. The author adds that surgery in future may aid in the treatment of the "hunchback's heart," and of the hypertrophied rheumatic heart, in young patients.

### 299. Purified Diphtheria Antitoxin.

G. RAMON (*Presse Méd.*, March 13th, 1926, p. 323) has prepared a diphtheria antitoxin and a tetanus antitoxin which have been purified by isolation of the pseudoglobulin from the protein. Their employment on a large scale in various Paris hospitals has shown that even in the treatment of diphtheria, in which large doses of serum are required, the incidence of serum sickness has been reduced, and its manifestations have been less grave than after the use of ordinary antitoxin. When purified serum was employed prophylactically the serum manifestations either did not occur at all or were very slight and transient, even if the individual had been sensitized by a previous injection. Thus among 150 children who received prophylactic injections of purified diphtheria antitoxin Lisné did not observe a single instance of serum sickness, and the same was found true in the case of tetanus antitoxin. Ramon has prepared a purified serum in which there is only a tenth part of the protein matter contained in ordinary tetanus antitoxin, though its antitoxic value is the same or higher. Moreover, the use of an antitetanic serum of high antitoxic value gives better results when tetanus has actually developed, and the size and number of the doses can be diminished.

330. L. JANVIER (*Thèse de Paris*, 1926), who records nine illustrative cases, states that Ramon's serum has the advantage of being half the bulk of ordinary serum though its therapeutic value is the same. Prophylactic injections in doses ranging from 1,000 to 4,000 units gave rise to mild and transient rashes in only 0.96 to 1.3 per cent. of the cases, whereas ordinary serum produces much more severe rashes in from 15 to 20 per cent. When used in the treatment of moderate and severe cases the purified serum caused only slight symptoms, such as erythema and urticaria, in 35 per cent., whereas the ordinary diphtheria antitoxin gave rise to symptoms which were often severe in from 35 to 70 per cent. Janvier adds that although serum sickness is still fairly frequent after the use of purified diphtheria antitoxin the milder character of the symptoms constitutes a considerable therapeutic progress.

### 301. Serum Treatment of Anthrax.

SCHUERMANS and VAN DER BEKEN (*Le Scalpel*, May 15th, 1926, p. 429) allude to the statistics of anthrax published in 1914 by Perrin and Modat relating to the hospital at Saint-Denis, which is an important centre for tanning and leather dressing. Whereas from 1875 to 1890 the mortality among seventy-two cases was 14 per cent., and among forty-seven cases from 1897 to 1904 10 per cent., the mortality among eighty-three cases treated by serum between 1905 and 1908 fell to 3.6 per cent., and there was not a single death in thirty-nine cases so treated between 1909 and 1911. They record the case of a man, aged 25, who was employed in a factory for carrying sacks. Serum treatment was instituted on the day after the appearance of a wound on the back of the neck, which was diagnosed as a malignant pustule from its clinical and bacteriological appearances. In the course of eight days he received 260 c.cm. of serum, of which 75 c.cm. was given intravenously and 185 c.cm. intramuscularly, followed by local applications of serum which seemed to hasten the separation of the slough. A sharp serum reaction followed, and complete recovery resulted.

### 332. Treatment of Uraemia in Children.

ACUTE nephritis in children, according to K. D. BLACKFAN (*Bull. Johns Hopkins Hosp.*, August, 1926, p. 69), differs from that of adults in that acute forms are far more common than chronic. In a series of forty-six cases only five were chronic, the forms most frequently encountered being the acute glomerular and the acute tubular. Increased arterial tension and the development of uraemic symptoms are characteristic of the former, whereas generalized oedema without rise in blood pressure is the outstanding feature of the latter. In

acute glomerular nephritis red blood cells are the conspicuous finding in the urine, the plasma protein is normal, and the non-protein nitrogen tends to increase in the blood; in the acute tubular form large amounts of albumin and lipid substances are found in the urine, the plasma protein is low, and the non-protein nitrogen in the blood is normal. Patients in the uraemic stage of acute glomerular nephritis were treated with intravenous injections of a 1 per cent. solution of magnesium sulphate and administrations of large amounts of magnesium sulphate by the mouth and rectum. Blackfan finds that the intravenous injections should be given slowly at the rate of 2 c.cm. per minute, the fall in blood pressure during the procedure being the best index as to the total amount to use. The good effect of this lasts from five to twelve hours, after which a rise in blood pressure with a return of the alarming symptoms can be expected; these are best combated by the administration of 1 to 1½ oz. of a 50 per cent. solution of magnesium sulphate by mouth every four or six hours, and 2 to 3 oz. of the same solution by the rectum every six hours. Excessive dehydration should be avoided. The author asserts that intracranial tension resulting from oedema of the brain is probably the causative factor of the symptoms in this form of uraemia and that arterial hypertension is probably the result of increased intracranial pressure.

## Ophthalmology.

### 303. Metastatic Carcinoma of the Choroid.

C. A. CLAPP (*Amer. Journ. Ophthalmol.*, July, 1926, p. 513) describes two cases of this condition, and reviews the literature in which 116 cases have been previously recorded. Metastatic carcinoma in this site occurs most frequently after breast cancer, but it has also followed primary carcinoma of the lung and less frequently of the stomach, thyroid, liver, and rectum. It may therefore be medullary, scirrhous, or adenomatous in type. It appears usually in the left eye, possibly in consequence of there being a more direct blood supply on this side. In one-third of the cases it was bilateral. The average duration of life after discovery of the disease in the eye was eight months.

### 334. Air Bubbles in the Vitreous.

R. FOSTER MOORE (*Brit. Journ. Ophthalmol.*, August, 1926, p. 418) describes a case of air bubbles in the vitreous; the globe had been punctured one-third of an inch behind the limbus by a steel fragment. On examination with the ophthalmoscope two air bubbles were seen floating about in the vitreous. The foreign body was removed with a giant magnet and next day the air bubbles had disappeared. Foster Moore states that to cause this condition the foreign body must enter the vitreous directly and not pass through the anterior chamber. The bubbles must be looked for within a few hours of the injury; in many cases they are multiple, appearing like a string of toy balloons of various sizes in contact with each other. They are quickly absorbed.

### 335. Ocular Findings in Addison's Disease.

A. L. BROWN (*Amer. Journ. Ophthalmol.*, June, 1926, p. 409) describes a case of Addison's disease in which a complete ophthalmological examination was made. The sclera were clear except for two dark spots near the limbus in each eye. The pupils were dilated and reacted readily to light, but only producing a miosis of 3½ mm. There was a marked difference between the calibre of the veins and arteries of the fundus, the veins being large and the arteries small. Around each macula and the disc there was a zone of pigment. These zones were joined by a thin pigmented strip running between the disc and macula. Both eyes were definitely hypotonic; with the Schiötz tonometer the tensions were found to be 14 in the right and 12 in the left.

### 305. Subconjunctival Echinococcus Infection.

G. R. HARE (*Arch. Ophthalmol.*, July, 1926, p. 367) describes a case of subconjunctival echinococcus infection. The patient, a woman aged 20, had complained of a gradually enlarging growth on the left eye during the previous two months. Examination showed a greyish cystic tumour, about the size of a pea, situated over the insertion of the internal rectus muscle. The cyst was excised through a conjunctival incision, and pathological examination confirmed its nature. Echinococcus infection of the ocular area has been fairly frequently observed, but chiefly in the orbit; a few cases of subretinal echinococci have been reported. In this case, on account of the superficial position, direct infection was considered, but would have required removal of the shell or its digestion by the tears. It was thought that most probably the embryo passed to its site through an exceptionally large muscular arterial branch.

OCT. 2, 1926]

# Obstetrics and Gynaecology.

**307.** SCHOCKART (*La Gynecol.*, May, 1926, p. 291) describes two cases in which pregnancy continued uneventfully after removal of fibroids by myomectomy. In the first, large interstitial myomata of the posterior wall of the lower uterine segment were removed between the tenth and thirteenth weeks of pregnancy; they had become incarcerated within the uterus, and the uterine cavity had to be opened, a myoma being in contact with the placenta. The second patient, a primipara aged 32, felt during the fifth month a hard tumour near the umbilicus; a sessile subserous myoma was diagnosed. Eight days later acute pain was felt in the region of the tumour, which remained tender; at operation a myoma the size of an egg was removed, which had slipped in between the uterus and the anterior abdominal wall and was compressing the omentum.

**308.** LANTIEROU (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, June, 1926, p. 349) describes a case of intraperitoneal haemorrhage during the puerperium caused by uterine myoma. The tumour, which was of the size of the fist and sessile in the neighbourhood of the left cornu, was recognized during pregnancy; a living child and vomiting occurred on the fifth and sixth days, and the tumour, which was tender, was thought to have become degenerated. No signs suggesting internal haemorrhage were present, but at operation about half a pint of blood was found in the abdominal cavity, having come from one of a number of varices on the surface of the myoma. Microscopically the tumour showed signs of aseptic necrosis.

**309.** A. ECKE (*Zentralbl. f. Gynäk.*, June 26th, 1926, p. 1688) records the case of a woman aged 35 who had suffered for four years from menorrhagia, and whose pregnancy terminated spontaneously at term twenty-one hours after rupture of the membranes and twelve hours after the onset of pains. A manual attempt to remove the placenta on account of post-partum haemorrhage was found to be very difficult, the uterus being the site of numerous interstitial myomata which had developed centripetally and over which the placenta was in places become firmly incorporated with the uterine wall. The decidua was defective. Part of the myometrium became detached with the placenta, some small portions of which hysterectomy was performed and the patient made a good recovery. The placenta accreta is attributed in this case, as in others, to the unfavourable influence of the presence of interstitial myomata on the nutrition of the placental site to and basal decidua. Ecke ascribes the fact that the myomata were largest and most numerous over the pregnant uterus to the increased vascularity of that region. He states that the presence of interstitial myomata in the third stage of labour involves three dangers, often combined, and a rigidity of the myometrium, which is mechanically prevented from contracting. With persistent haemorrhage resolute treatment is necessary; prolonged attempts to remove manually or instrumentally a placenta accreta are ineffective and waste time, and hysterectomy, if necessary, should be early lest haemorrhage and shock prove fatal after operation.

## Abnormal Labour.

**310.** MARY C. DEGARIS (*Med. Journ. of Australia*, July 3rd, 1926, p. 6) defines a normal labour as one in which the uterine contractions act thoroughly efficiently, leading in a short time to the spontaneous delivery of a healthy baby and causing but little or no distress or pain to the mother. She cites Mackenzie's work on symptoms and their interpretation and McCollum's newer knowledge of nutrition, and concludes that if fertility, viability, duration of life, and vigour depend largely on the diet, and the mother and child are similarly affected, some influence on the processes of labour may also be expected. Pain is regarded as an indication of faulty labour, of faulty uterine action, or of uterine inertia. Unsuitable diet, focal sepsis, and the condition of the blood are probably important factors in causing uterine inefficiency. The observation of cases is therefore required, and it is suggested that childbearing should be regarded as the occurrence of one clinical entity in successive stages which precipitate but does not cause complications; the illness may occur during pregnancy, but is not wholly due to pregnancy. DeGaris also recommends an attempt to discover the root causes of the numerous variations in labour, and more especially the conditions governing the intensity of labour pain. She

emphasizes the importance of uterine inertia as the central and fundamental problem in obstetrics, and advocates co-operation between the physiologist and the clinician—the first being concerned with chemical deficiencies in the diet, the second investigating the possibility of treatment by glandular or chemical products. She adds that a thorough knowledge of the physiology of labour, with special reference to the action of the uterine muscles, is the *sine qua non* for the conduct of normal labour, just as a knowledge of the mechanics of labour is essential to the conduct of an abnormal labour.

## Ferocious Vomiting in Pregnancy.

**311.** J.-L. AUDEBERT and A. GALT-GASPARROU (*Paris Méd.*, June 19th, 1926, p. 593) remark that in cases of hyperemesis gravidarum in which purgation and treatment of uterine infections or malpositions have failed to effect improvement, the physician must be on guard against inducing abortion too early, so that the foetal life is sacrificed unnecessarily, or too late, at a time when the mother's life can no longer be saved. If the family or personal antecedents of the patient point to an hysterical etiology immediate and absolute isolation is essential, followed by treatment by suggestion if necessary. Suggestion may take the form of an "operation" consisting only in examination under ether anaesthesia, or the exhibition of methylene blue pills, the patient being told to expect cessation of the vomiting if the urine becomes blue. The effect of many treatments, such as application of tampons, and correction of a history or stigma of the same category. In the absence of a history or stigma of hysteria the vomiting should be combined with purgation, hydrotherapy, intrarectal and hypodermic injections of toxæmic origin; isolation should be hypodermic and blood transfusions. In certain cases, whether toxæmic or fundal, purgation, and treatment by adrenaline or proposed as montally hysterical, treatment fails; the authors discuss various signs which have been described or proposed as justifying in these cases the termination of pregnancy, such as pulse frequency is of importance; very quick rates, such as 140 a minute, are not inconsistent with vomiting, but a quick rate which becomes progressively augmented at repeated examinations, in spite of efficient treatment, is of grave import, and points to the necessity for induction of abortion. Loss of weight is a sign of little value; the case is quoted of a patient who had lost more than two stone in four weeks yet was cured by isolation and suggestion. Signs of hepatic insufficiency—subicteroid tinge or the smell of acetone in the breath—are of grave prognostic significance, but in exceptional cases are consistent with vomiting which is curable by suggestion. Careful study of the systolic and diastolic blood pressure is of importance; as Fieux and Ballard have shown, the former is diminished and the latter increased in hyperemesis gravidarum, and with improvement the systolic and diastolic pressures rise and fall respectively. The always present, but an increasing oliguria in spite of treatment justifies the speedy termination of pregnancy. An increase of urea in the urine combined with an increase of the purin bodies, acetone and especially aceto-acetic acid persisting and increasing in amount in the urine, an increase of the urinary amino-acids are all grave signs, more significant than an increased ammonia-urea coefficient. In examination of the blood acetonaemia and increased urea content point to kidney blockage and are of grave significance. Morbid nervous manifestations—delirium, hallucinations, hyperpyrexia, and polyneuritis—are ominous signs, and if they have appeared induction should be performed at once, although it may very possibly prove to be too late.

## Premature Detachment of the Placenta.

**312.** W. E. WELZ (*Amer. Journ. Obstet. and Gynecol.*, June, 1926, p. 842) reports eight cases of premature detachment of the normally situated placenta. He states that purely traumatic cases, as distinguished from those in which the "accidental haemorrhage" is of toxæmic origin, are rare and are usually susceptible of effective treatment by vaginal delivery. He recognizes two types of toxæmic cases with almost unvarying results. The first is the dangerous and severely toxic cases in which myometrial haemorrhages are present, as shown clinically by tenderness and tenderness of the uterus with almost uncontrollable bleeding and shock. In this type Porro section appears to be the only successful mode of treatment. The second variety is the less dangerous case in which the uterine muscle is not the site of haemorrhage, and the uterus is lax before delivery. Birth by the natural route is possible, and post-partum haemorrhage may be controlled by uterine stimulation and packing.

## Pathology.

### 313. The Epidemiology of Pneumonia.

J. P. POWELL, R. M. ATWATER, and L. D. FELTON (*Amer. Journ. Hygiene*, July, 1926, p. 570) have made a study of the distribution of pneumococci in the throats of a sample population in Boston. The volunteers, ninety-three in number, consisted of schoolboys, medical students, laboratory workers, and hospital nurses, of whom none had apparently come into contact with cases of pneumonia more frequently than the general population. The examination continued from September, 1923, to March, 1924. After preliminary cleansing of the mouth the patient was instructed to gargle with 30 c.cm. of saline; the washings were then centrifuged for one hour, and the sediment injected into the peritoneal cavity of a mouse. Six hours later fluid was withdrawn and used for preparing cultures and studying the morphology of the organisms. The standard taken for a pneumococcus was a Gram-positive, capsulated diplococcus, bile-soluble, fermenting inulin, and in the case of the fixed types agglutinating with specific serum. The virulence was tested by injecting 0.5 c.cm. of a 1 in 100, a 1 in 10,000, and a 1 in 100,000 dilution of an 18-hour broth culture into mice. Strains that failed to kill in the lowest dilution were regarded as avirulent. Of the ninety-three persons who were examined monthly all but four carried pneumococci at one time or another; 44 per cent. had a fixed type coccus, while 56 per cent. had either no pneumococci or Type 4 cocci. In three instances three different types were recovered from the same patient. There appeared to be a definite seasonal fluctuation in the presence of pneumococci in the throats; this held good for all types. The maximum percentage of positive findings was in September and in January; in November the fixed types practically disappeared. Figures show that the maximum mortality from pneumonia in the population of Boston was in December and March; that is to say, the maximum incidence of pneumococci in the throat—judging by the sample population—was reached about two months previous to the maximum mortality from pneumonia. Experiments indicated that the fixed types did not remain in the throat as a rule for more than a month. Types 1 and 3 appeared to be more virulent than 2 and 4. The authors' results support the conclusion that the incidence of pneumonia depends on the coincidence of infection by a pathogenic pneumococcus with a lack of resistance in the individual.

### 314. The Blood in Different Kinds of Anaemia.

F. G. FINLEY (*Canadian Med. Assoc. Journ.*, July, 1926, p. 765) agrees with Weicker (1854) that the blood constitutes approximately one-thirteenth of the body weight; the blood plasma may be taken as 5 per cent. and the corpuscles as 4 per cent. of the body weight, the average volume of blood being 85 to 90 c.cm. per kilo of weight. The blood plasma varies little, so that deficiency in corpuscles is mainly responsible for changes in blood volume, which, according to Keith, is reduced by a quarter in obesity and increased in pregnancy. Concentration of plasma may occur in carcinoma of the oesophagus, in gas poisoning, and in shock. Variations of this kind in normal and morbid conditions are slight, and the colour index and blood count give a fair indication of the degree of anaemia. The red cell count of blood in the veins may be as much as 10 per cent. higher than that of the capillaries, except in pernicious anaemia, where the reverse occurs. Finley attributes the high colour index of pernicious anaemia to the larger average size of the cells, whereas in secondary anaemia from haemorrhage the cells are slightly smaller than normal. The three principal causes of blood poverty are haemorrhage, haemolysis, and defective function. The presence of haemolytic agents can be diagnosed by the delayed van den Bergh reaction in the blood, by increase of urobilinogen in the urine, and by the faint yellow tinge of the skin. Defective formation may be due to syphilis, senile changes, wasting diseases, or the exhaustion following overactivity in sepsis; lead, arsenic, and mercury, after prolonged administration, cause exhaustion. The rapidly fatal aplastic anaemia seems to be almost exclusively due to the destruction of the blood-forming elements in the marrow. In anaemia from moderate haemorrhage recovery is rapid, but the colour index and blood count are lower at first owing to dilution. Recovery is mainly dependent on the rate of fluid absorption, and there appears to be a relation between the haemoglobin content and the rate of absorption, the latter falling when the haemoglobin is at 20 per cent. and incomplete until 40 to 50 per cent. In pernicious anaemia, haemolysis and marrow regeneration proceed coincidentally, the latter predominating at times. Finley mentions the cord affections in pernicious anaemia, and the characteristic remissions in the disease: an apparently healthy interval of seventeen years was recorded in one case which ended fatally.

6.0 P

He emphasizes the importance of searching for the ova of intestinal parasites in doubtful cases of anaemia, especially where eosinophilia is present, and of a thorough examination of the rectum or pelvis for evidence of malignant growth in middle-aged patients with secondary anaemia. Careful examination of the blood is required in cases of achlorhydria or when there is a complaint of painful tongue or tingling extremities. In aplastic anaemia there is no regeneration, the marrow being yellow and fatty; as a rule there is no haemolysis and no remission; the patient rarely lives more than three months. Finley believes that cirrhosis of the liver is probably not constant in Banti's disease and that affections of the splenic-portal vascular system are too inconstant to be regarded as primary.

### 315. Inhibition of the Growth of *B. coli* by Acid.

A. H. JOHANSEN and E. J. WARBURG (*Acta Med. Scand.*, August 6th, 1926, p. 91), prior to the treatment of infections of the urinary tract in human beings, tested the effect of acid and of urotropine on the growth of the colon bacillus *in vitro*. Broth tubes were adjusted to varying degrees of acidity, inoculated with *B. coli*, and incubated at 37°C. for seventy-two hours; after two, four, six, and eight hours subcultures were transferred to ordinary broth to see whether the organisms were still alive. The results showed that in broth of pH 5.15 growth was delayed for forty-eight hours; in broth of pH 4.64 no growth occurred at all in the original tube, and subcultures taken after eight hours as a rule failed to grow. It would therefore appear that when exposed in a nutrient medium to an acidity of pH 4.64 *B. coli* is killed in about eight hours. In another series of experiments tubes of broth adjusted to varying degrees of acidity were inoculated with *B. coli*, and subcultures made in succession every four hours. The growth in each tube was read after twenty-four hours' incubation. It was found that in broth having an acidity of pH 5.0 no growth occurred after the fifth or sixth subculture. That is to say, frequent transfers of *B. coli* in a medium unfavourable to growth resulted in the disappearance of the organism. The authors considered that if the urine of patients suffering from coli infections of the urinary tract could be rendered highly acid, and if the patient were to micturate at frequent intervals, the organism should be placed in such unfavourable conditions as to render its survival improbable. This idea was carried into practice. The patients were given calcium chloride or ammonium chloride in amounts sufficient to render their urine acid to methyl red—namely, pH 5.5 or under. Urotropin was given to some of the patients. Of 35 cases in which the acid treatment was tried a perfect cure with sterile urine was obtained in 20, generally in two to three weeks. Of the remaining cases many were complicated with other conditions and did not react so well. By laboratory experiments it was demonstrated that urotropine had little effect on *B. coli* except in an acid medium; and that even in an acid medium it did not exert its maximum effect for about twenty-four hours; this latent period is consumed in the liberation of formaldehyde. Since acid alone is able to sterilize the urinary tract in a fairly high proportion of uncomplicated cases, the authors add that it is difficult to form a judgement on the effect of urotropine *in vivo*.

### 316. Urinary Infection in Vitamin A Deficiency.

G. FRONTALI (*Riv. di Clin. Pediatria*, August, 1926, p. 505) in a controlled experiment with young white rats found that seven on a diet deficient in vitamin A but given soya oil and pericarp extract died with xerophthalmia, small multiple cutaneous abscesses (2), and a constant infection of the urinary tract, whereas the remaining nineteen animals were unaffected. In four cases small multiple abscesses were found in the kidney, visible macroscopically, and in two others abscesses were found on micropathological examination; one of these cases had perivascular abscesses in the cortex and medulla. In six out of the seven there was pus in the renal pelvis on one or both sides; the pelvic wall was infiltrated with leucocytes and had leucoplastic zones in it. Four had a urethritis, and in all seven there was more or less severe cystitis with submucous infiltration, epididymic metaplasia, and the formation of epithelial pearls; *B. coli* was isolated from the pus, and in two cases *Staphylococcus aureus* as well. Frontali considers this constant infection of the urinary tract of great significance in view of the difficulty of producing *B. coli* infection in laboratory animals by either the ascending route or by blood infection. He thinks that in these rats the infection was due to lowered resistance brought about by their lack of vitamin A. Conditions pathologically analogous are found in the pyelocystitis of children who, being bottle-fed or on a deficient diet, suffer from malnutrition and underdevelopment. Frontali considers his results should indicate an alimentary and vitaminic treatment for infantile pyelocystitis.

### Medicine.

#### 317. Stenosis of the Aortic Isthmus.

J. T. KING, jun. (*Arch. Intern. Med.*, July, 1926, p. 69) remarks that although congenital cardio-vascular lesions are as a rule multiple and present confusing signs leading to a diversity of diagnoses, yet in the case of congenital stenosis of the aortic isthmus the condition can be recognized clinically with very considerable ease. Four cases are described, in which the condition was detected during life; of these two were slight stenosis of the aorta and the other two more or less complete obliteration of the vessel at the level of the entrance of the ductus arteriosus. Necropsy records show that the diagnosis is usually only made after the patient's death. It occurs more often in men than in women, and at any age after birth; it is not incompatible with prolonged periods of hard physical work. The symptoms that may be present are shortness of breath, palpitations, myocardial weakness, nocturia, cramps in the legs, and intermittent claudication. Pulsation may be detected in both inter-scapular regions, passing from above downwards; this sign is considered by King to be the cardinal manifestation of the condition. Pulsation is usually more marked in the upper limbs than in the lower. Pulsating superficial collateral vessels take an oblique course over the back of the thorax downward towards the spine; the intercostal arteries are dilated. The blood pressure is relatively higher in the arms than in the legs, and in the right arm rather than the left. The right radial pulse may feel larger than the left, and in the latter the apex is relatively delayed and rounded. Systolic murmurs are heard over the areas of inter-scapular pulsation, the enlarged collateral vessels; sometimes also over the aortic arch anteriorly or the whole aorta posteriorly. A bibliography is appended.

#### 318. Spontaneous Pneumothorax.

A. J. A. KOELEN-MID (*Nederl. Tijdschr. v. Geneesk.*, June 12th, 1925, p. 2139), who records three illustrative cases, states that spontaneous pneumothorax is a rare occurrence and that it is usually not due to tuberculosis. It occurs suddenly in persons who have hitherto been apparently healthy, or have suffered from pain in the chest and shortness of breath. In more than half the cases some kind of physical exertion has preceded the attack. On examination the characteristic signs of dry pneumothorax are found; only exceptionally is a little serous fluid or effused blood detected in the pleural cavity. Complete recovery as a rule follows sooner or later without any sequelae, and an unfavourable course is very rare. On post-mortem examination in such cases a ruptured subpleural emphysematous vesicle is found to be the cause of the pneumothorax. The emphysema may be local or general, and is sometimes interstitial, especially in children. The emphysematous vesicles are frequently present at the apices of the lungs in the neighbourhood of old tuberculous scar tissue, where they may reach the size of a cherry. Active tuberculosis is seldom if ever found, even after recovery from spontaneous pneumothorax.

#### 319. Cerebro-spinal Syphilis.

G. NAGASAKA (*Arbeit. a. d. Neur. Inst. a. d. Wien. Univ.*, May, 1926, p. 239) asserts that it is a well established fact that the meninges form the chief point of attack in the central nervous system for the syphilitic virus, the spirochaetes gaining entrance to the cerebro-spinal fluid and so to the meninges by the lymph spaces in the adventitia. The meningeal changes may exist for many years without giving rise to any clinical symptoms, as is illustrated by the case of Cestan and Risher, who found diffuse chronic meningitis in a patient whose only symptom was immobility of the pupils, and Ostertag's three cases of chronic syphilitic meningitis in which hardly any symptoms were present. On the other hand, Pette has reported cases in which symptoms developed relatively early—namely, a few months after appearance of the primary lesion, death following shortly afterwards. At the autopsy severe meningitis was found, with inflammatory lesions in the adjacent parenchyma. Nagasaka has recently had the opportunity of examining six cases in which chronic meningitis had obviously lasted several years before it gave rise to clinical symptoms which rapidly proved fatal. The patients were all about 60, an age at which vascular changes are the rule even apart from syphilis. The meningeal process, indeed, was not the cause of the sudden appearance of the clinical symptoms, which were the outcome of a vascular process produced partly by syphilis and partly by

purely senile changes. A characteristic feature of all the cases was the presence of severe meningeal lesions, of which the most typical was mesarteritis, and the intact condition of the adjacent parenchyma. The adventitia was enlarged, and in some places was invaded by the meningeal inflammation. The intima might be relatively little affected or show considerable changes leading to vascular occlusion. In all the cases the cerebral changes were accompanied by severe arthritis and cardiac diseases, as frequently occurs. A combination of aortic syphilis with cerebral disease is very frequent, aortic changes being noted in 34.8 per cent. of Frisch's cases of cerebral syphilis, and in 38 per cent. of those of J. H. Musser and A. E. Bennett.

#### 320. The Sedimentation Rate in Certain Industrial Conditions.

V. M. PALMIERI (*Studium*, February, 1926, p. 50) has investigated the sedimentation rate of the red corpuscles in individuals subjected to various forms of hard work, or employed in an overheated atmosphere, such as glass workers and stokers, with the following results. The sedimentation time was found to be constantly shortened in individuals engaged in hard work, and as constantly prolonged in those employed in an overheated atmosphere. These changes in the sedimentation rate could be detected, though in a diminished degree, even forty-eight hours after the factors in question had ceased to operate. The degree of acceleration or of prolongation of the rate did not appear to be related to the quantity of work performed, the duration of the fatigue, the stay in the overheated atmosphere, or its height of temperature, but might be regarded as an expression of a varying individual biological reaction to definite stimuli. Palmieri adds that these changes from the normal sedimentation rate show that certain industrial conditions are associated with physiological changes which should be carefully recorded, since they may supply valuable data for a rational prophylaxis, and for the medico-legal estimation of definite pathological conditions or causes inherent in certain industrial conditions.

### Surgery.

#### 321. An Unusual Cause of Inguinal Hernia.

ACCORDING TO E. FELDMANN (*Zentralbl. f. Chir.*, July 24th, 1926, p. 1892) inguinal hernia may follow stretching of the skin and subcutaneous tissue by an increase of intraperitoneal pressure. He describes the case of a workman, aged 63, who had observed for three or four months swellings in both groins; at the time of admission to hospital these swellings were each as large as a walnut. A double radical cure was performed without difficulty, but on the following day the patient had early symptoms of ileus, and slight rectal haemorrhage occurred after an enema. When the operation wounds had healed a digital exploration revealed the presence of an early carcinoma of the rectum. The hernias were not of the ordinary type, but the radical operation had been performed before any symptom of rectal carcinoma had appeared. Feldmann concludes that no operation on an inguinal hernia in an elderly man should be performed until a complete and general examination has been made. Hernial protrusions have been known to be produced by an increase of intra-abdominal pressure, which occurs frequently in elderly patients, and which may be due to partial intestinal obstruction by carcinoma, to the increased pressure resulting from prostatic hypertrophy and urethral stricture, or to the persistent cough of chronic bronchitis. In children inguinal hernia may be caused by dysuria resulting from phimosis or it may occur during an attack of whooping-cough.

#### 322. Carcinoma of the Prostate.

H. C. BUMPUS (*Surg., Gynecol. and Obstet.*, August, 1926, p. 150) reviews 1,000 cases of prostatic carcinoma treated at the Mayo Clinic up to January, 1925. The average age of these patients was 65 years. In approximately one-half the disease appeared between the 60th and 70th year, in no case was it seen before the 42nd, and in only four prior to the 45th year. Prostatic neoplasms occurring before 40 should be sarcoma. The initial symptoms, mainly those associated with benign hypertrophy of the gland, were frequency, difficulty of urination, and pain. Retention was rare, and gross haematuria was never noted. The later symptoms also simulated those of benign hypertrophy, but in malignant

disease there was less evidence of obstruction. The amount of residual urine was comparatively small, the phenol-sulphonaphthalein readings were high, and, except late in the disease, microscopic examination was of little value. In 243 of the cases metastases were demonstrable, the lymphatic system being the earliest and most frequently involved; next in frequency came the osseous system, especially the sacrum and adjoining portions of the spine and pelvis. Metastases were also found in the lungs, spinal cord, skin, liver, and kidneys. Treatment was surgical, with radium, or a combination of the two. The results from surgical treatment alone were poor, and Bumpus does not think this form is advisable when the disease has advanced sufficiently to be diagnosed positively. In order that radium treatment might be successful the gland was thoroughly irradiated, the radium being applied through the urethra; emanation-bearing seeds were inserted directly into the gland as well as through the perineum and over the rectal surface. The doses given averaged a little over 2,000 milligram hours, and the subsequent average life of the patients was 22 months. Results were also poor in those cases in which prostatectomy was performed after irradiation of the gland. Thorough irradiation of the prostatic capsule and seminal vesicles following prostatectomy gave encouraging results, and Bumpus believes that this method offers the greatest possibility of cure. When there was but little residual urine the daily use of a catheter was sufficient; if the obstruction was more severe, suprapubic cystostomy was performed with beneficial results.

### 323. Cholecystoduodenostomy.

G. P. MULLER (*Annals of Surgery*, July, 1926, p. 95) enumerates the indications for "internal drainage" of the gall bladder as irremovable obstruction of the common duct, injuries and diverticulum of the common duct, and calculous cholecystitis in later life complicated by pancreatitis. All recent writers give the site of the anastomosis as the stomach or duodenum. Muller uses a rubber tube in making the anastomosis with good results. After suturing the gall bladder to the duodenum a mushroom catheter is passed through a stab hole into the gall bladder and fastened by a circular purse-string. The other end is inserted into the duodenum and inverted by a similar suture. The first suture is then continued anteriorly. This method is simple and the tube prevents closure of the opening. No omentum is wrapped round the joint and no leakage has occurred. In three cases recorded the results were excellent and the jaundice was relieved. If the condition is due to chronic pancreatitis the anastomosis appears to be of great value and to relieve the symptoms satisfactorily.

### 324. Artificial Pneumothorax in Hydatid Diseases of the Lung.

F. DÉVÉ (*Arch. Méd.-Chir. de l'App. Resp.*, April, 1926, p. 125) reports that spontaneous recovery occurs in 90 per cent. of the cases of hydatid cysts situated in the centre of the lung which open spontaneously into the bronchi, and artificial pneumothorax is rarely required. Sometimes, however, the natural process of recovery is tedious, so that Forlanini's operation appears applicable in the following series of cases: (1) when the natural process of recovery, observed by pericolic radiological examination, is delayed, especially if prolonged expectoration of hydatids is complicated by recurrent haemoptysis; (2) when the cyst situated in the centre of the lung gives rise to a persistent cavity containing air and pus, indicating a loss of plasticity in the tissue of the lung surrounding the cyst, due to absence of pleural adhesions; (3) when in the presence of vomicae, accompanied by deterioration of the general condition, radiological examination does not show the exact site of the cavity which requires evacuation.

## Therapeutics.

### 325. Adrenaline Injections in Cardiac Failure.

IN view of the increasing use of intracardial injections of adrenaline for heart failure, M. PETZETAKIS (*Arch. des Mal. du Cœur des Vaisseaux et du Sang*, August, 1926, p. 513) has given experimental intravenous injections of freshly prepared and standardized adrenaline solutions to a number of normal individuals between the ages of 20 and 35 years. Intravenous injections of 1 c.cm. of 1 in 300,000 to 1 in 100,000 strength caused no objective disturbance, but with solutions of 1 in 60,000 to 1 in 20,000 the majority of subjects, after an interval of a few seconds, exhibited pallor and palpitation. With solutions of 1 in 10,000 these symptoms were increased: with an intravenous dose of 1 c.cm. of 1 in 4,000 every subject complained of dyspnoea and violent palpitation, while the face became pale and syncope appeared to be imminent.

When the dose was increased to 1 in 1,000 syncope, necessitating the injection of a cardiac tonic, occurred; this dose, the author concludes, should never be exceeded. The injection of 1 c.cm. of solutions of from 1 in 200,000 to 1 in 60,000 produced a very brief fall in systolic pressure, followed quite frequently by a variable degree of hypertension. When these doses were increased to 1 in 8,000 there was an initial rise of blood pressure, becoming shorter as the dose was increased and followed by a very definite fall. Petzetakis adds that large doses of adrenaline produce definite sinus or nodal arrhythmia, due to stimulation of the sympathetic or of the intracardiac centres. The vagotropic action of adrenaline is inhibited by preliminary injection of atropine. Adrenaline gives rise to syncope only when excessive doses are injected. In patients anaesthetized by chloroform it is particularly necessary to exercise great caution in the injection of adrenaline, since chloroform produces vagal irritability. The author does not condemn the endocardial injection of adrenaline in syncope, but he calls attention to the danger of large doses; in no case should a dose of 0.25 mg. be exceeded. He advises great caution in the use of adrenaline in the Stokes-Adams syndrome; adrenaline is not cumulative, and therefore a moderate dose can be repeated at intervals when necessary.

### 326. Serum Treatment of Erysipelas.

K. E. BIRKHAUG (*Journ. Amer. Med. Assoc.*, May 8th, 1926, p. 1411) has treated sixty cases of moderately severe erysipelas by intramuscular injection of erysipelas antistreptococcus serum in doses of 100 c.cm. of the unconcentrated and from 15 to 20 c.cm. of the concentrated serum. He found that when it was administered during the first three days of the disease it caused a prompt amelioration of toxic depression, a critical fall in temperature and pulse rate, prompt fading of the erysipelatous lesions, and rapid absorption of the blebs and oedema within the affected areas. In late cases the serum had a very favourable action on the general toxic depression, although repeated injections might be necessary completely to neutralize the circulating toxin in the patient's blood. After each injection of the serum there was a critical fall of temperature and pulse to normal within twelve to eighteen hours. In some cases the symptoms quickly returned, and a second dose was necessary to bring about complete recovery.

### 327. Treatment of Syphilis by Bismuth.

J. L. GRUND (*Urol. and Cut. Rev.*, May, 1926, p. 284) emphasizes the value of bismuth in cases resisting treatment by salvarsan or mercury or both, as evidenced by the persistence of syphilitic manifestations. His method of administration was as follows. The contents of one ampoule containing 0.2 gram of potassium bismuth tartrate, together with a small amount of a local anaesthetic, were injected intramuscularly once every five to seven days. Each patient received a minimum of 2.4 grams or a maximum of 3 grams potassium bismuth tartrate. Unoward reactions were very rare. When a local reaction in the form of swelling or persistent pain occurred the dose was reduced to one-half, and then again increased until the entire amount was received without discomfort. Grund ignores the appearance of the blue line unless stomatitis is present. No cases of albuminuria or cachexia were observed; in most of the patients the bismuth seemed to act as a tonic. Grund concludes that bismuth should replace mercury as an adjunct to salvarsan in the treatment of syphilis.

### 328. Insulin-Glucose Treatment of Shock.

D. FISHER (*Surg., Gynecol. and Obstet.*, August, 1926, p. 224) states that shock may be considered to be the result of an intense stimulation of the kinetic nervous system by such agents as physical exertion, emotion, and trauma, which lead to physical changes in the kinetic system, and, if carried far enough, exhaust it. The usual methods of treatment have been directed towards maintenance of the fluid volume, elevation of blood pressure, and retention of body heat; the fundamental cell pathology, the internal asphyxia and acidosis, and the initiating factors have been disregarded. Fisher believes that in shock an internal asphyxia and acidosis with checking of the oxidative processes result in a state of exhaustion, and that this state is primarily caused by a sudden derangement of the central nervous system. To combat the shock he judges that some method should be employed whereby the body can be furnished with a substance giving rise to an immediate supply of energy, maintaining that supply so long as is necessary, and furnishing fluids to keep up the circulating fluid volume. In insulin-glucose treatment of shock 500 to 2,000 c.cm. of a sterile 10 to 15 per cent. solution of glucose are injected intravenously. The total duration of administration should be at least one hour, and preferably two to four hours. This precaution is,

he adds, extremely important when any large amount of fluid is introduced into the veins, for dilatation of the right heart is a real danger. The amount of insulin used depends upon the amount of glucose injected; for every 3 grams of glucose one unit of U 20 insulin may be used. The total amount should be divided into two equal doses, one part being given about fifteen minutes after the administration of glucose has started, and the remainder at the end of the administration. It is advisable to have ready a hypodermic of adrenaline, so that any reaction may be easily and quickly dealt with. So long as glucose appears in the urine there is no danger of an insulin reaction. In support of this treatment Fisher maintains that the heat energy supplied to the cells by the rapid oxidation of the glucose at a time when the normal oxidative processes are checked is a most vital factor in starting the process of recovery of the cells. By this method he has successfully treated 31 cases of shock; he has also used it with gratifying results in the pre-operative preparation of surgical cases as a prophylaxis when the subject was not a good risk, and to check the incessant vomiting of acute peritonitis. Ochsner has also employed it in all cases of pernicious anaemia when blood transfusions have had no effect.

## Anaesthetics.

### 322. Spinal Anaesthesia.

A. CERNEZZI (*Arch. Ital. di Chir.*, August, 1925, p. 237), as the result of using spinal anaesthesia in more than 3,000 cases during the last twenty years, has come to the following conclusions. (1) Spinal anaesthesia is contraindicated in patients who present any considerable degree of arterial depression. (2) As a general rule it is advisable to prevent excessive hypotension by a subcutaneous injection of 30 to 40 cgm. of caffeine one hour before spinal anaesthesia. (3) It is best to use a needle of small calibre for the injection, so that there is no danger of not making the injection with the necessary swiftness and the least force. (4) It is not rational or prudent to withdraw more than a few drops of spinal fluid before the injection. (5) Change of the patient's position, which is of the utmost importance as regards the course of the anaesthesia, should be performed slowly and without jerky movements. (6) The patient should always keep his head flexed on the trunk during and a few hours after the operation. (7) Trendelenburg's position should not be adopted until ten minutes after the injection. (8) Spontaneous evacuation of liquid faeces during spinal anaesthesia indicates anaesthesia of a considerable part of the spinal nerves (fourth to eighth dorsal) which give issue to the rami communicantes for the sympathetic nerves.

323. R. BROGLIO (*Arch. Ital. di Chir.*, June, 1926, p. 639) records his observations on 1,146 cases of spinal anaesthesia performed from March, 1923, to March, 1926, in the surgical department of the Civil Hospital at Belluno. The cases were divided into two groups. The first, which formed the great majority, included operations on the hypogastric, inguinal and scrotal regions, the external genitalia, perineum, anal, sacral and gluteal regions, and lower limbs. The second group comprised operations on the abdominal viscera, abdominal wall, and lower half of the thorax. The anaesthetic solution consisted of equal parts of stovain and sodium chloride (0.10 gram). The ages of the patients ranged from 11 to 82. 611,603 in which the sexes were recorded 656 were males and 334 females. In almost all cases the puncture was carried out in the sitting position. In spite of slight and transient drawbacks such as headache, rise of temperature, vomiting, backache, and retention of urine, the patient derives the following advantages from spinal anaesthesia: (1) almost entire elimination of the grave risk of post-operative complications, especially those affecting the respiratory system; (2) avoidance of the unpleasant feeling of suffocation which is inseparably associated with anaesthesia; (3) absence of the long and painful stage of "coming round"; (4) less likelihood of vomiting, which is almost constant in other forms of anaesthesia; (5) diminution, if not entire exclusion, of the danger of death from syncope; (6) non-interference with the renal function; (7) elimination of bad after-effects on the stomach, such as gastritis due to other intoxication. The surgeon, on the other hand, reaps the following benefits from spinal anaesthesia. He saves time, because complete anaesthesia is induced while the patient is being got ready for operation; he is not forced to keep an eye on the patient, and there is no likelihood of having to suspend the operation in order to perform artificial respiration. There are no severe post-operative complications, and the anaesthesia is regular throughout the operation. In another paper (*Arch. Ital. di Urol.*, May, 1926, p. 621) Broglio reports on 80 genito-urinary operations under spinal anaesthesia. In 77, or nearly 100 per

cent., complete anaesthesia was effected; 17 had no symptoms whatever, 7 had vomiting or retching, and only 2 had retention of urine, one for twenty-four hours and the other for nine days. The remainder showed only slight rises of temperature. Collapse occurred in only one case, and did not last longer than five minutes.

### 331. Post-operative Acidosis in Children.

P. K. DIXON (*Irish Journ. Med. Sci.*, June, 1926, p. 267) reviews the literature, including the recent paper by Jeans and Tullerman (*Epitome*, February 28th, 1925, para. 214), and reports his observations on 210 children, of whom only five, or 2.4 per cent., showed clinical signs of acidosis, while post-operative acetonaemia was present in 77 per cent. out of 165 examined. Anaesthesia was induced in the first case by pure ether, in the second by a mixture of chloroform and ether in the proportion of 1 to 20, and in the third by a mixture containing two parts of chloroform to three of ether. These three cases were examples of recurrent abscess following the removal of a gangrenous appendix. In the fourth case, one of cleft palate, ether was administered for one hour. In the fifth case chloroform was given for only five minutes for the curettage of cervical glands. The symptom common to all five cases was urgent and continuous vomiting; two patients were drowsy, and two very restless. The fifth case was much less severe and the child was fairly bright all the time. In the four severe cases the operation lasted half an hour or more. None of the cases was absolutely clean, and three were markedly and continuously septic. Dixon's conclusions are as follows. The incidence of post-operative acidosis diminishes slightly with increase of age, and the incidence of acetonaemia is slightly greater after the administration of chloroform than of ether. Prolonged anaesthesia increases the probability of post-operative acetonaemia. It is not possible by examination of the urine before the operation to estimate the probability of clinical acidosis. Acetonaemia is not a contraindication to operation. The administration of glucose causes a considerable diminution of the incidence and duration of post-operative acetonaemia, but sodium bicarbonate does not affect its duration.

### 332. Sacral Anaesthesia in Urology.

O. GRANT (*Urol. and Cut. Rev.*, June, 1926, p. 336) has performed the following operations under sacral anaesthesia alone: cystoscopy, urethral catheterization in tuberculous bladders, internal urethrotomy, resection of vesical tumours, perineal section of urethral stricture, insertion of perineal radium needles, fulguration of bladder tumours, lithotripsy, litholapaxy, suprapubic cystostomy, suprapubic cystotomy for calculi, and suprapubic prostatectomy. The anaesthetic used was novocain prepared not more than ten days previously in capsules with sodium chloride and sodium bicarbonate. Each capsule contained 0.6 gram of novocain, 0.1 gram sodium chloride, and 0.15 gram sodium bicarbonate. The contents of one of these capsules were emptied into 30 c.cm. of boiling water and the solution allowed to boil for twenty seconds. After the solution was cooled 5 minims of adrenaline were added. For caudal anaesthesia about 20 c.cm. of this solution was sufficient, while for transsacral anaesthesia 30 c.cm. was needed. The injection required twenty to thirty minutes to induce complete anaesthesia. Sacral anaesthesia was found to be of special value in irritability of the bladder due to calculi, tuberculosis, ulcer, or tumour, and enabled the bladder to be distended painlessly to two or three times its normal capacity. In open operations on the bladder the relaxation was as complete as under ether anaesthesia. No untoward effects were noted in any case. Grant's conclusions are on follows: (1) sacral anaesthesia is a safe and simple method; (2) it may be used in consulting-room practice for difficult bladder cases, as well as for minor surgical procedures on the bladder and rectum; (3) there is no interference with any vital function of the body—the heart, lungs, and kidneys not being in the least affected; (4) it enables the patient to be placed in any posture and permits the continual ingestion of fluids, which is so essential in renal disease.

## Obstetrics and Gynaecology.

### 333. Prevention of Puerperal Infection.

D. H. BESSESEN (*Med. Journ. and Record*, July 7th, 1926, p. 27) believes that one important source of puerperal infection has not received sufficient attention hitherto. A chronic bacillary vaginal infection exists in the majority of apparently healthy women; a large number of these infections are streptococcal, and of these a considerable percentage are of the haemolytic type. The author practises the following routine disinfection of the vagina immediately before the commencement of labour. After shaving, washing, and giving an enema, the

parts are painted with a 10 per cent. solution of mercurio-chrome. A large sterile speculum is lubricated with sterile glycerin, containing 2 per cent. mercuriochrome and 0.6 per cent. of tincture of iodine diluted to  $\frac{3}{4}$  per cent.; it is then inserted into the vagina and 5 c.cm. of the same solution is injected into the vaginal vault. A plug of sterile gauze is inserted in the introitus in order to retain the solution. The mercuriochrome-iodine-glycerin solution is deposited on the vaginal mucosa as the blades of the speculum are withdrawn. The author adds that the proportions of the antiseptics have been worked out by prolonged experiments, in order to combine the maximum effectiveness with the minimum degree of irritation. The viscid solution adheres to the vaginal mucosa for a considerable time, and Bessen claims that it prevents the mechanical infection of the uterus by the alternating descent and retraction of the head during the second stage of labour. He maintains that this solution is relatively non-toxic and that the head coming down into such a vagina will carry back a coating of this antiseptic and paint the interior of the uterus with this substance rather than with infectious material. The author also condemns the Cr  d   method of expressing the placenta, since by pressing the hand on the large relaxed uterus the cord is forced downwards into the vagina: when pressure is removed the contaminated cord is withdrawn into the uterus. Early rupture of the membranes prolongs the second stage and thus increases the risk of infection by the alternating descent and ascent of the foetus. Manual removal of a returned placenta also increases the danger, as the hand carries a large number of bacteria from the vagina to the fundus uteri.

### 334. Intrauterine Asphyxia.

ACCORDING to N. LOUROS and H. M  LLER (*Zentralbl. f. Gyn  k.*, July 17th, 1926, p. 1897) Seitz was the first, in 1903, to report that administration of chloroform to the mother improves the condition of the labouring foetal heart, probably by diminishing the degree of pressure exercised on the foetus by the uterus between the pains. Frey suggested therapeutic application of this finding and in 22 of 35 cases noted restoration of failing foetal heart action during chloroform inhalation. The present authors report the results of administering 5 to 8 drops of chloroform a minute in 39 cases in which the foetal heart-beat had become slowed to a hundred or less a minute during labour; cases in which the slowing followed rupture of the membranes and those of slight asphyxia during expulsion of the head are excluded. They conclude that this treatment is successful and the only one necessary in cases in which the sole cause of foetal distress is deficient relaxation of the uterus between its contractions. In 16 of their cases the inhalation of chloroform was without restorative action on the foetal heart, and artificial acceleration of delivery was necessary; invariably in these cases there was obstruction of the circulation through the umbilical cord, which was looped firmly once or twice round the neck, and knotted or prolapsed. It is suggested that administration of chloroform is a test which should be tried in all cases of intrauterine asphyxia with slowed foetal heart; an absence of improvement as shown on auscultation during two successive intervals between pains indicates obstruction of the cord and points to the necessity for hastening delivery.

### 335. Treatment of Menstrual Disorders.

E. NOVAK (*Therapeutic Gazette*, May 15th, 1926, p. 315) discusses the treatment of menstrual disorders in the light of recent physiological research. He thinks that since the amenorrhoea associated with increasing obesity is undoubtedly of endocrine causation organotherapy appears to be the most logical and least harmful form of treatment, and though at present frequently unsatisfactory in its results, Novak considers that the further development of biochemical methods will eventually lead to improvement in this direction. In the treatment of dysmenorrhoea atropine, given to the point of saturation and commencing several days before the period is expected, often relieves when analgesic drugs fail; in some cases where this is not effective the presence of a definite causative anatomic lesion, such as a small interstitial or submucous myoma, must be suspected. Pituitary, ovarian, or thyroid extracts are disappointing. Dilatation of the cervix often gives good results and stem pessaries are to be condemned. The functional uterine haemorrhage of puberty, when mild, tends to spontaneous cure, but when severe, diagnostic curettage is indicated and in most cases results in permanent cure. Novak himself has had good results following the daily use of pituitary extract. In persistent functional bleeding near the menopause complete cessation follows radiotherapy, and though this treatment, if cautiously used, may be advocated in younger patients, the danger of producing permanent amenorrhoea and sterility must be explained to the patient; many gynaecologists prefer to rely upon a repetition of the curettage rather than have recourse to radium in young women.

## Pathology.

### 336. Production of Vitamins in Cow's Milk.

H. CHICK and M. H. ROSCOE (*Biochem. Journ.*, 1926, vol. 20, No. 3, p. 632) have studied the effect of diet and of sunlight on the vitamin A and D content of the milk of a cow kept under different conditions for varying lengths of time. The vitamin A content was estimated by the power of the milk to induce growth in rats on a dietary free from this vitamin, and the vitamin D content by its power to prevent rickets in rats fed on a low phosphorus rickets-producing diet. It was found that the vitamin A (growth-promoting, anti-xerophthalmic) content was dependent on the diet of the cow, being at a maximum when the cow was fed on fresh green food and least when the cow received a winter feed of cereals and roots. Exposure to sunlight had no influence on the vitamin A content of the milk. The vitamin D (growth-promoting, antirachitic) content depended chiefly upon the degree of insolation of the cow; but there was a certain amount of evidence suggesting that a dietary of fresh green food contributed to its appearance. The maximum content of vitamin A and D was present in the milk when the cow was out at pasture in the summer. Butter made from milk possessing antirachitic power was still potent after storage for more than two years in a freezing-chamber. The authors draw attention to the bad effect on the fat-soluble vitamin content of the milk of keeping milch cows in stalls. They state that such milk probably contains very little vitamin D, and is therefore unsuitable for the nutrition of infants and young children.

### 337. Gas Gangrene Bacilli in Melaena Neonatorum.

W. HERGT (*Monatsschr. f. Kinderheilk.*, July, 1926, p. 515) records two cases of melaena neonatorum characterized by the occurrence of Fraenkel's gas gangrene bacillus, as shown by the results of culture and inoculation of animals. The clinical course of the two cases was quite different: one infant rapidly succumbed, while the other survived. At the necropsy of the first case gas gangrene bacilli were cultivated from the upper, middle, and lower parts of the small intestine, the caecum, spleen, and liver. Subsequent examination of the meconium of six infants, all but one of whom were breast-fed, showed the presence of the gas gangrene bacilli in two, while the rest were negative. The conclusion that the gas gangrene bacilli possessed a pathological significance in these two cases seems justified by the large number of bacilli in the meconium at a very early stage, and the presence of the bacilli in the small intestine and internal organs. The infection was probably derived from the maternal birth passages.

### 338. The Mode of Action of Saline Purgatives.

H. COHEN (*Quart. Journ. Med.*, April, 1926, p. 249) by direct determinations of the magnesium content of the blood after magnesium sulphate has been administered by the mouth and by intramuscular injection, and from similar experiments with magnesium chloride, concludes that the purgative action of these salts is not due to the absorption of magnesium into the blood. Since an examination of the literature showed that the evidence was too conflicting and the methods previously employed were too indirect to justify definite conclusions, it was not until the introduction of an accurate method for the estimation of magnesium in small quantities of serum that the problem could be approached upon the above lines. Cohen shows that the oral administration of these salts in purgative doses is unaccompanied by any alteration in the magnesium content of the blood serum, and that though intramuscular injection increases the serum content 50 to 100 per cent., in no case was it accompanied by purgative effects.

### 339. Lactic Acid Retention in Pregnancy Toxaemia.

H. J. STANDER and A. H. RADELET (*Bull. Johns Hopkins Hosp.*, August, 1926, p. 91), using the method of Clausen, have found that in pregnancies complicated by low kidney reserve or by nephritis there is an increase in the lactic acid in the blood which disappears as the patient improves. This lactic acid increase may be due to renal impairment sufficient to produce retention of non-protein nitrogen, to the decomposition of protein, or to fat. Clausen stated that whenever the circulation or the process of oxidation becomes insufficient the rate of removal of lactic acid will be less than the rate of its production, so that the lactic acid concentration will rise and the alkali reserve of the tissues will fall. Stander and Radelet hold that the factors which may possibly play a role in the accumulation of lactic acid in the two types of pregnancy toxaemias (low kidney reserve and nephritis) are decreased elimination of lactic acid, decreased oxidation and interference with the resynthesis of lactic acid into glycogen, and a possible disturbance of the hydrogen-ion concentration of the blood.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 310. Familial Pernicious Anaemia.

S. E. DORST (*Amer. Journ. Med. Sci.*, August, 1926, p. 173), from his own observations in eleven cases of familial pernicious anaemia, as well as from the literature of the subject, concludes that in this disease there may be an important hereditary factor. He asserts that the old conception that pernicious anaemia is strictly a blood disease has changed; it is now thought that the blood changes bear a similar relation to the disease as such changes do to the entire syndrome of lead poisoning. In both diseases a persistent low-grade toxæmia is now considered to be the essential causative factor. According to Dorst, Hurst has stated that the fundamental predisposing cause of this anaemia is achlorhydria, which may be the result of constitutional and congenital absence of the gastric juice, or may be acquired. This condition removes the normal bactericidal function of the gastric secretions, permitting the development in the upper portion of the small intestines of a bacterial flora which gives rise to neurotoxins and hæmolytic poisons. Dorst believes that achlorhydria gastrica is a sign of grave clinical importance; that every patient presenting this condition should be considered as a potential case of pernicious anaemia; that the administration of hydrochloric acid should be started immediately, even though there are no gastric symptoms; and that all members of a family in which pernicious anaemia has been found should be thoroughly examined and have gastric analyses made so that administration of the acid may be started at once if necessary. In both fully developed and potential cases of pernicious anaemia large doses of hydrochloric acid should be given, as small doses fail to bring the acid contents of the stomach to the minimum normal acidity, though it is advisable to start with smaller doses and gradually increase them, since otherwise diarrhoea may be produced. The dose recommended is a half to one drachm of dilute acid well diluted with water or with well-sweetened lemonade or cider four times daily. The dilution of the acid should be in the proportion of not less than one drachm of the dilute (10 per cent.) acid to eighteen ounces of water or other medium. This is divided into smaller amounts, part being taken before, part with, and part after the meal. Dorst adds that since treatment continues throughout life, the co-operation of the patient is important.

### 311. Disappearance of the Tuberculin Cutaneous Reaction during Measles.

R. DEBRÉ and KAROLA PAPP (*Ann. de méd.*, June, 1926, p. 576) record their observations on 223 children suffering from measles on whom more than 1,000 cutaneous Pirquet tests were made. In 37 children at one time or another there was a positive reaction, while in the remaining 192 the reaction was never positive during their stay in hospital. In 35 cases the reaction became positive again after having been negative during the eruption. Like Pirquet, the authors found that the reaction never became positive before the fourth day of the rash. In 50 per cent. it reappeared on the fifth, sixth, or seventh days—that is, before the end of the first week. The return of the power to react to tuberculin is always progressive, the first anti-reaction being negative, the second doubtful, the third macular, the fourth papular, and the fifth vesicular. In three cases the reaction remained positive throughout the disease. In 15 cases with a positive reaction during the decline of measles active tuberculosis was present. The authors did not find that the reappearance of the reaction was more rapid in subjects with active disease than in those with latent tuberculosis.

### 312. Fatal Tréparsol Poisoning.

E. MAY (*Dull. et Mém. Soc. Méd. des Hôp. de Paris*, July 8th, 1926, p. 1176) describes a case of tréparsol poisoning in a woman, aged 43. She had become pregnant a fourth time after two miscarriages, preceded by the birth of a healthy child. Although neither the patient nor the husband presented any clinical or serological signs of syphilis, four days' treatment by increasing doses of tréparsol was prescribed as a precaution. The total quantity taken was approximately 2.5 grams of the drug, and the patient's health appeared to be excellent. During the first two days she had no symptoms, but on the third day, when she took three compressed tablets of tréparsol, she noticed a sensation of weight in her stomach and some colic, but did not report these symptoms. On the

fourth day she took four tablets, and next day the slight digestive disturbance was more marked. On the fifth day she awoke feeling unwell; she vomited a blood-stained fluid. She later became suddenly aphasic and very quickly lost consciousness. When seen by May she was deeply comatose, with a very congested face and marked stertor. There was left hemiplegia and frequent violent convulsive spasms of all four limbs. Severe attacks of hæmatemesis followed, and death occurred about twelve hours after the onset of symptoms. The author has been unable to find any record of a similar case, but states that these arsenical preparations, even when given by the mouth, may be dangerous. He thinks that the original doses should be small and their effects be carefully watched; progressively increasing doses should not be employed. The patient should be constantly under observation when taking tréparsol by the mouth, as when arsenobenzols are being given intravenously. FLANDIN (*ibid.*, p. 1177) states that so rapid an increase of the dose does not correspond to any usual scheme of treatment: the increase should be only week by week and not from day to day.

### 313. Weil's Disease without Jaundice.

H. A. LAMPE (*Nederl. Tijdschr. v. Geneesk.*, June 26th, 1926, p. 2870) reports a case of Weil's disease in a child aged 2 years, who, four days after falling into a ditch which was full of rats, developed a febrile condition which lasted several weeks, without any jaundice, enlargement of the spleen, or hæmorrhages. The Widal test for typhoid and paratyphoid fever was negative, and no typhoid or paratyphoid bacilli were found in the stools. The blood contained staphylococci only. The serum, however, agglutinated *Spirochaeta icterohaemorrhagiae* in a dilution of 1 in 10,000, and later of 1 in 100,000. Intraperitoneal injection of the urine into a guinea-pig had no result. Recovery followed an illness of four months.

## Surgery.

### 314. Subperiosteal Irreducible Fracture of Radius.

A. SCHLESINGER (*Zentralbl. f. Chir.*, August 14th, 1926, p. 2073) refers to E. Müller's article on this subject (see *Epitome*, March 20th, 1926, para. 319), and describes the case of a boy, aged 15, who had a fracture of the radius 2 inches above the styloid process, with considerable displacement of the distal fragment, definitely abnormal mobility, and slight swelling. No crepitus was felt, and there was very little pain. The reduction of the displacement was apparently quite successful, and a dorsal plaster splint was applied. When this was removed ten days later a skiagram showed very pronounced displacement of the fragments, though pain was entirely absent. A diagnosis of subperiosteal fracture with irreducible displacement was made. At the operation the periosteum was found to be intact; the callus formation had filled entirely the periosteal sheath three weeks after the accident. There was considerable irregularity of the distal fragment below the line of the fracture, and it was clear that the only way of obtaining a good anatomical result was to separate the fragments, the periosteum being divided and sutured over the site of the fracture. The operation wound was closed, scarcely any irregularity remained, and the appearance of the limb became normal. In this case all the symptoms described by Müller were present—increased mobility, no crepitus, slight swelling, very little pain, and persistence of the displacement after attempts at reposition. Schlesinger adds that when these symptoms are present it is evident that ordinary treatment has failed and that an operation is indicated.

### Osteomyelitis Variolosa.

E. J. HUENEKENS and L. G. RIGLER (*Journ. Amer. Med. Assoc.*, July 31st, 1926, p. 295) report a case, in a boy aged 4, which is the first recorded example of osteomyelitis variolosa occurring during the acute stage of small-pox. Eight days after the appearance of the eruption swollen and tender joints were noted in both arms and legs; one week later the patient complained of pain in the neck, which was stiff and tender. X-ray examination revealed a symmetrical widespread destructive process at the epiphyseal line of the long bones, and in the first cervical vertebra, which became dislocated, without, however, causing any serious symptoms. The acute condition of the bones continued for about two

months after the eruption of small-pox had disappeared, being accompanied by a rise of temperature and by leucocytosis. Repair followed finally with almost complete recovery, except for the dislocation of the first cervical vertebra. The rarity of osteomyelitis variolosa is shown by the fact that although the authors examined by x rays a large number of small-pox patients, many of whom complained of pains in the limbs and joints, no similar case was discovered.

### 346. Aneurysm of the Splenic Artery.

H. NÄHER (*Deut. Zeit. f. Chir.*, August, 1926, p. 118) records a case of aneurysm of the splenic artery in a woman, aged 54, who had noticed a slowly increasing swelling in the left hypochondrium for over a year. Recovery followed operation. Näher has also collected fifteen other cases from the literature of aneurysm of the splenic artery in patients aged from 25 to 60. In all cases there was a history of pain in the region of the spleen, or at least in the upper part of the abdomen. The character of the pain ranged from a dull ache to attacks of violent colic, and the symptoms lasted from a few hours to several years before death or the performance of an operation. In three cases fainting attacks and loss of consciousness occurred, being caused, not by internal haemorrhage, but by hysteria or pressure on the solar plexus. Five patients suffered from gastro-intestinal disturbance and vomiting. In all but two cases there was dullness and resistance in the splenic region or upper part of the abdomen, which was more or less tender. Several patients when first seeking advice had profound anaemia, and were in a state bordering on collapse. In only three instances was the possibility of an aneurysm suspected, but its localization was never defined. Operations were performed on ten patients, four of whom recovered, while all those who did not undergo operation died. In most of the cases the main trunk of the artery was affected close to the hilus. The size of the aneurysm varied from that of a hazel nut to that of a man's head. In about half the cases two aneurysmal sacs were present, and in some cases there were as many as three aneurysmal dilatations of the artery. Two of the cases were due to trauma. There was no mention of syphilis being responsible in any case, though it is doubtful whether a special examination to detect it was always made. Arterio-sclerosis was mentioned in only one case, and in most of the cases the etiology was obscure.

### 347. Acute Cholecystitis in Children.

M. ZELIGS (*Arch. of Pediat.*, July, 1926, p. 485), who records an illustrative case, states that disease of the gall bladder in children is apparently rare. According to Snyder, only about eighty cases were reported between 1722 and 1922, acute suppurative cholecystitis being very uncommon. Reid and Montgomery in 1920 were able to find only about twenty cases on record, most of which were complications of typhoid fever. Zelig's case was in a girl, aged 12 years, who, about two months after the onset of typhoid fever, developed all the symptoms of acute cholecystitis. The pain, tenderness, and rigidity over the gall bladder were relieved by non-surgical duodenal drainage, a 40 per cent. solution of magnesium sulphate being used. A pure culture of typhoid bacilli was obtained from the bile, but after a single intravenous injection of 15 c.cm. of a 1 per cent. solution of mercuriochrome 220 the typhoid bacilli disappeared from the bile.

## Therapeutics.

### 348. Injection Treatment of Varicose Veins.

J. A. SICARD and L. GAUGIER (*Presse Méd.*, June 2nd, 1926, p. 683) review the literature, including the paper by J. Dunbar (*JOURNAL*, January 3rd, 1925, p. 14) on the treatment of varicose veins of the leg by injections, and record the results of nearly ten years' experience of the method. During the war Sicard had observed that the intravenous injection of luargol, an arsenical preparation rich in sodium, caused rapid sclerosis of the veins in the area injected without producing any pain or motor or trophic disturbance. He therefore determined to apply the method to the treatment of varicose veins, and being convinced that the arsenical element was not responsible for the result decided to employ sodium carbonate, for which he afterwards substituted sodium salicylate, as the former was liable to cause sloughing of the subcutaneous tissue. Binioidide of mercury (Montpellier and Lacroix), quinine (Génévrier), and sodium citrate (Troisier) have also been employed for the same purpose. The authors use solutions of sodium salicylate ranging from 20 to 40 per cent., commencing with a dose of 2 c.cm. of the 20 per cent. solution, and followed two or three days later by 2 or 3 c.cm. of the 30 to 40 per cent. solution. In successful cases 6 to 8 cm. of the vein becomes obliterated after the first

injection, and after four or five injections complete sclerosis of moderate sized varicosities is effected. The authors think that binioidide of mercury in 1 per cent. solution should be reserved for cases in which syphilis is suspected, and for those which are refractory to treatment by sodium salicylate. Injections of quinine hydrochloride (0.40 gram), combined with urethane, are likely to cause severe pain and oedema, although the end-results are excellent. The treatment of varicose veins by injection into them of substances causing sclerosis is contraindicated in plethoric subjects with hypertension, as well as in cases of heart and renal diseases. They add that the method should never be employed in cases of long-standing deep phlebitis.

### 349. The Therapeutic Value of the Antirachitic Vitamin of Cod-liver Oil.

M. FLAMINI (*La Pediatria*, June 15th, 1926, p. 625) finds that the non-saponifiable fraction ("ostelin") extracted from cod-liver oil by Zucker's method in a daily dose of 5 to 15 m for a normal infant renders the faeces constantly acid, the normal reaction in the healthy breast-fed child, or increases their acidity. As a rule 3 to 4 m twice a day was sufficient to keep the faeces acid. On a daily dose of 2 to 3 grams of calcium lactate an acid stool would become alkaline, but with the addition of 3 m of ostelin twice or three times a day the faeces regained their acidity. In marasmic babies with poor digestion the change came about more slowly and required larger doses (5 to 8 m). This is of importance, since regular bowel action is normally associated with an acid stool. Flamini appends a curve showing the effect of the vitamin on the stools of a bottle-fed baby aged 3 months and suffering from hard, grey, infrequent, alkaline, offensive motions; these were converted into creamy, acid, yellowish, regular, inoffensive (diminished putrefaction) stools. Large doses may cause hyperacidity, resulting in green stools and diarrhoea, and this is counteracted by giving calcium lactate. The vitamin increases the absorption of calcium through the intestinal wall, and simultaneously it stimulates the production of steapsin and increases fat metabolism, with greater formation of soaps (absorbed), a corresponding increase of fatty acids, and a diminution of neutral fats in the stools. The effect of the vitamin in increasing the body weight is shown in curves of 32 infants given doses of 3 to 5 m two to five times a day. This increase is attributed by Flamini to the improved intestinal absorption and the improved nutrition of the tissues due to more active assimilation. The acidity of the blood is diminished, and Flamini therefore used the vitamin in the treatment of symptoms due to acidosis, such as cyclical vomiting (one case cured in one month), infantile eczema (9 cases cured in three weeks by calcium lactate and ostelin), and predisposition to tuberculosis. Three cases of spasmodicophilia were cured, he thinks, by the vitamin increasing the penetration of calcium into the cells of the sympathetic. This vitamin also raises the blood pressure and benefits cutaneous vasomotor disturbances such as urticaria, which are due, he thinks, to vagotonia or hyposympatricotonia, its action being similar to that of adrenaline.

### 350. The Therapeutic Action of Manganese Citrate.

L. NORMET (*Paris méd.*, July 31st, 1926, p. 102) finds that the metallic citrates, especially manganese citrate, have a special therapeutic action in infections and recommends the following formula: Sodium citrate 52 grams, magnesium citrate 10 grams, ferro-potassium tartrate 3 grams, and manganese citrate 1 gram, water to one litre. Normet states that an hour after an intravenous injection of 0.25 c.cm. per kilo of body weight the patient's temperature rises, and there is shivering and profuse sweating; the degree of fever produced varies, but is greater in very emaciated patients. This febrile reaction occurs after the injection of any dose of manganese citrate larger than 0.04 gram. When the dose is reduced the reaction is less, and it disappears completely when the dose is less than 0.02 gram. The author suggests that these symptoms are due to the energetic oxidation produced by ferro-potassium tartrate and manganese citrate. There is no danger or general disturbance, but the injections are ill borne by very anaemic patients. In these cases Normet employs minute doses of manganese citrate (about 0.001 gram), which appear to increase the haemoglobin content. He believes that manganese citrate is a very valuable remedy in the treatment of infections, especially in neurotoxic cases, such as influenza, cerebro-spinal meningitis, rubeola, and haemoglobinuric jaundice. It is said to be less valuable in enteric fever, although it produces a brief fall in temperature. The author suggests that manganese citrate modifies the toxins by the abstraction or addition of oxygen. The systemic disturbance described above may be avoided by adding to the solution 5 per cent. of neutral glycerin, which retards ionization and oxidation of the salts without interference with the therapeutic action. The author proposes to

employ the solution in all cases in which neurotrophic toxins resist the usual therapeutic measures. In an epidemic of influenza the results were very satisfactory; one patient with influenzal bronchopneumonia was cured after a single injection.

351.

**Local Action of Stovarsol.**

L. CHÉARD (*Arch. de l'Inst. Pasteur d'Algérie*, June, 1926, p. 340) reports a case of phagocœmic syphiloma of the lower lip, which responded to external treatment only with stovarsol. The lesion showed all the syphilitic characteristics, and though the *Treponema pallidum* could not be demonstrated the blood had a positive Wassermann reaction, and four days after the conclusion of treatment the patient gave birth to a child presenting all the signs of congenital syphilis. Treatment consisted solely in scraping the ulcer, and touching it once daily with an aqueous solution of stovarsol (1 gram in 20 c.c.m. distilled water), followed by a large vaseline compress. No internal medication was given, and cure resulted in less than five days.

**352. Intraspinal Injections in Syphilis of the Nervous System.**

V. FOSSATI (*Rev. Sud-Americana di endocrinologia*, July 15th, 1926, p. 600) reports the treatment of 13 patients, aged from 30 to 54, with syphilis of the nervous system, principally tabes, by intraspinal injections of their own salvarsanized serum; the injections were associated with the intramuscular administration of mercury (bimiodide, benzoate, salicylate, or grey oil) and bismuth (tartro-bismuthate or iodo-bismuthate of quinine) and with intravenous injections of neo-salvarsan. He found that the intraspinal method greatly increased the efficacy of the other injections, cases of severe tabes of rapid evolution showing remissions and improvements which were not observed when intravenous and intramuscular injections only were employed. Patients treated by intraspinal injections presented an exacerbation of their symptoms of the Herxheimer type, but the reaction was only transitory. During the treatment the general condition might deteriorate for a short time, and therefore it seemed best to give only a few injections, with a fortnight's interval between each. While intraspinal treatment is in progress lymphocytosis of the cerebro-spinal fluid is stated to be frequent, but as a general rule examination of the fluid is negative at the end of treatment; the Wassermann and Nonne-Apert reactions were also negative. Fossati adds, however, that clinical improvement has no close relation to biological reactions.

**Dermatology.****353. Dermatitis Exfoliativa Neonatorum.**

M. SZARKA (*Monatssch. f. Kinderheilk.*, May, 1926, p. 253) states that though it is sixty years since dermatitis exfoliativa was described as an autonomous disease by Ritter from his observation of 297 cases, the essential nature of the condition has not yet been satisfactorily explained. It is regarded by Behrend as identical with pemphigus foliaceus in the adult, and, although Ritter persistently asserted that the two diseases were distinct from one another, the relation of dermatitis exfoliativa neonatorum to pemphigus still remains unsettled. Knoopfelmacher and Leiner reported the case of an infant who at the age of 5 days developed pemphigus neonatorum, which became transformed into dermatitis exfoliativa and ended fatally in six days. They also recorded the case of a male infant who died of dermatitis exfoliativa at the age of 10 days, while his sister, who had never been washed in the same bath, developed pemphigus contagiosus two days later. Szarka now relates the history of female twins, one of whom had pemphigus neonatorum, while the other nine days later developed typical dermatitis exfoliativa; both recovered. These cases support the view held by Knoopfelmacher and Leiner, as well as by Wioland, that dermatitis exfoliativa is really a severe form of pemphigus, and, in spite of Ritter's view, is a contagious disease.

**354. Curable Cutaneous Induration in the Newborn.**

A. B. MARFAN and G. L. HALLEZ (*Le Nourrisson*, July, 1926, p. 226), who record eight cases, two of which came under their own observation, have introduced the term "curable cutaneous induration in the newborn" in place of scleroderma neonatorum, as it is distinct from scleroderma in the adult, and has nothing to do with scleroma neonatorum. The condition is due, as Lieberthel and Bernheim-Karrer have shown, to traumatism during or immediately after birth, caused by application of forceps, prolonged compression during passage through the pelvis, artificial respiration, or

flagellation. The first lesions usually appear three or four days after birth as nodules and plaques. The size may be that of a small pea, or the lesions may be much larger and occupy the whole of the upper limbs or back. They are slightly raised above the level of the skin, and are at first of a dark red or violet hue, but they progressively lose colour and show a branny degeneration. The skin in the parts affected is of an almost woody hardness and does not pit on pressure. The sites for the lesions are those exposed to obstetrical trauma—namely, the cheeks, chin, and lower jaws from the application of forceps, and the back, shoulder, postero-external aspect of the arms, and buttocks from flagellation or compression in the pelvis. The lesions rapidly attain their full size, remain stationary for several weeks or months, and then gradually disappear without ever ending in ulceration or suppuration. Examination of the skin lesions shows two principal changes—namely, complete disappearance of fat and a more or less active inflammatory reaction; and two less important changes—a few haemorrhagic areas and some oedema of the connective tissue spaces. No micro-organisms have been found. According to Bernheim-Karrer, the initial lesion is necrosis of the subcutaneous fat, with small haemorrhagic extravasations, followed by an inflammatory and oedematous reaction. No active treatment, such as massage or inunction, is required, but the skin of the parts affected must be protected from injury and contamination of any kind.

**355. Concurrent Herpes Zoster and Varicella.**

A. C. ROXBURGH and P. H. MARTIN (*Brit. Journ. Derm. and Syph.*, July, 1926, p. 286) review the literature, including the cases reported by Aviragnet, Huber, and Dayras (*Epitome*, May 9th, 1925, para. 465), and Gautier and Peyrot (*ibid.*, June 27th, 1925, para. 622), and record the case of a man, aged 41, who developed a well marked eruption of herpes zoster on the left side of the neck and head in the areas supplied by the second and third cervical nerves concurrently with an eruption of varicella on the trunk and limbs. Fourteen and fifteen days later a girl, aged 18, and a child of 3½, who had been in contact with the patient, developed typical varicella. The authors think that cases of this kind may be regarded as due either to the dissemination of the varicella virus, which in the first instance attacked certain nerve roots only, or to the mere coincidence of unrelated diseases.

**Obstetrics and Gynaecology.****Accidental Haemorrhage.**

356.

L. PRAGER (*Zentralbl. f. Gynäk.*, July 17th, 1926, p. 1908) states that in Norway so much attention has been focused of late on premature detachment of the normally situated placenta that the diagnosis is not infrequently made by placenta that the cases are admitted to hospital at an early stage, when there is some chance of saving the foetal life. The condition has been diagnosed in 0.6 per cent. of labours since 1914 at Oslo, and in a similar proportion of cases at Copenhagen: this is compared with the reports of the Rotunda Hospital at Dublin, where accidental haemorrhage (0.74 per cent.) has a higher incidence than placenta praevia (0.56 per cent.). It must be remembered, however, that in recent years, especially in Scandinavia and Ireland, cases of slight accidental haemorrhage with few clinical symptoms have been included; here the diagnosis has sometimes been made by the expulsion of blood clot with a placenta which shows on examination signs of accidental haemorrhage. The characteristic symptoms and signs in typical cases are: (1) sudden pain in the lower abdomen or back; (2) haemorrhage, —internal (concealed), external, or both—with pallor, distress, fainting, and impaired pulse; (3) an enlarged, hard, distended uterus which is so painful and sensitive that the foetal parts and heart beat are recognized with difficulty; (4) the absence in the early stages of uterine contractions, and even when labour is progressing, great difficulty in distinguishing periods of uterine contraction and relaxation. The delivery of the child is quickly followed by that of the placenta, accompanied by recent and older blood clots. In cases with few clinical symptoms, other than slight ante-partum bleeding, the diagnosis is clinched during labour by detection in the placenta of saucer-shaped depressions to which old blood clot is attached on the maternal side. The differential diagnosis is most difficult from acute abdominal conditions outside the uterus—for example, appendicitis and torsion of tumours. Placenta praevia gives a picture of collapse in the absence of an "acute abdomen." Uterine rupture in the absence of contracted pelvis should cause little difficulty in diagnosis, and occurs usually at a comparatively late stage. In about a hundred cases reviewed by Prager, trauma, shortness of the cord or pulling thereon, and late rupture of the

membranes played no etiological part: among fifty cases, however, there were only sixteen in which albuminuria was not present, and of the series of a hundred, no fewer than twelve suffered from eclampsia during the current or a previous pregnancy. Non-albuminuric patients as a rule showed the least extensive detachments, but one patient with complete separation of the placenta and 3.3 kilograms of blood clot had a urine free from albumin. Among fifty cases spontaneous birth occurred in thirty-four instances and maternal mortality was 8 per cent. At Caesarean operations or autopsies subserous and intramuscular bleedings in the uterus were almost constant findings, and free blood-stained fluid was frequently present in the abdomen. Foetal mortality was about 60 per cent., and as a rule foetal survival was found to be incompatible with detachment of more than one-half of the placenta.

### 357. Axial Torsion of the Uterus.

L. DIEULAFÉ (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, June, 1926, p. 392) records two cases in which torsion of the uterus caused acute symptoms. In the first a nullipara, aged 32, who had not had specially copious menses, was seized suddenly with violent abdominal pain and vomiting, followed by painful and frequent micturition. Two days later meteorism and a swelling of the right kidney were noted, and thirteen days afterwards, the abdomen having become less swollen and less tender, a large myoma of the uterus was recognized. At operation the uterus was found to be rotated almost completely around the isthmus, and the position of the myoma was consistent with compression of the right ureter during the acute stage. In the second case a married woman, aged 24, who had had four months' amenorrhoea, suffered suddenly from severe abdominal pain and shock. A cystic tumour, regarded as an adnexal inflammatory lesion or an extrauterine gestation sac, was apparently present in the right fornix and the uterus was enlarged. At operation the right angular region was found to be the site of uterine pregnancy and to have become axially rotated. Pregnancy continued after the rotation had been corrected without uterine fixation other than by abdominal pads and bandages.

### 358. Puncture of the Cisterna Magna in Intracranial Birth Injuries.

B. S. DUNHAM (*Amer. Journ. Obstet. and Gynecol.*, June, 1926, p. 833) thinks that many new-born babies with intracranial haemorrhage fail to receive benefit from lumbar punctures because the spinal canal is not entered or is blocked by blood clot, or only blood is withdrawn in small quantity from punctured vessels of the spinal plexus. In such cases, he states, puncture of the cisterna magna is equally effective therapeutically, and in experienced hands is no more dangerous; at this site the blood vessels are chiefly extradural, so that operative contamination by blood is unlikely. After anterior flexion of the head the position of the posterior rim of the foramen magnum is located by deep palpation and a lumbar puncture needle inserted, a few millimetres above, until the occiput is touched. The needle is then displaced downwards so as to glide under the posterior edge of the occipital bone, and is next pushed forward and upward in line with the mid-point between the glabella and anterior fontanelle until the "give" of the needle indicates that the occipito-atlantal ligament has been pierced. Dunham has made twenty-seven cistern punctures in ten new-born infants, nine of whom had intracranial haemorrhage as indicated by ocular disturbances, cyanosis, localized twitchings or generalized convulsions, and respiratory, cardiac, or temperature disturbances. The punctures varied in number from one to five in each patient, and the beneficial effect was often prompt and decided. Six babies recovered and five still appear to be without mental or physical defects at ages from nine to twenty-four months.

### 359. Births following Caesarean Section.

WILLE (*Zentralbl. f. Gynäk.*, July 10th, 1926, p. 1857) states that during the last fifteen years abdominal Caesarean section has been performed in 357 out of 28,917 deliveries, or in 1.2 per cent., at the Women's Clinic of the Charité Hospital, Berlin. In 43 cases Caesarean section was performed twice, in 19 three times, and in one case four times. In cases where there was no indication for a fresh Caesarean section, expectant treatment was a laparotomy, and in 19 spontaneous delivery occurred. In another 16 delivery through the vagina required the aid of forceps. In contrast with these favourable cases there were four examples of rupture of the uterus. The second pregnancy was not responsible for this rupture, which was really due to lack of asepsis and faulty technique in the primary Caesarean section. Wille adds that when rupture occurs complete extirpation of the uterus is essential. The prognosis is grave, as the mortality is 25 per cent.

718 D

## Pathology.

### 360. Closure of the Appendix.

R. FINALY (*Nederl. Tijdschr. v. Geneesk.*, August 14th, 1926, p. 765) states that the appendix was ligatured in 1904 by Ssobolew, who among other histological changes found atrophy of the muscularis mucosae and lymph follicles. Finaly now reports his own observations on ligaturing the appendix in rabbits, his conclusions being as follows. Experimental closure of the vermiform appendix in the rabbit, as in pathological closure in man, causes first a dilatation and then a cystic state of the organ. The contents are usually sterile and may consist of pure mucus, mucus mixed with intestinal contents, or a creamy or brittle mass formed mainly of polymorphonuclear leucocytes or lymphocytes. The wall of the cyst is usually thin, but may be thick; the inner surface is pale and glistening. Diverticula may arise in connexion with the cysts in the rabbit, just as in man. The contents of the cyst may pass out into the abdominal cavity, giving rise as in man to a condition resembling pseudomyxoma peritonei, which consists not only of a gelatinous and mucinous degeneration of the peritoneum, but also leads to the formation of nodules or cysts containing mucus by implantation on the peritoneum of the escaped contents of the appendix. The caseous mass which has passed out into the peritoneal cavity in most cases gives rise to a chronic adhesive peritonitis. After multiple ligation of the appendix acute gangrene of the wall develops, although the artery is not involved, as the result of sudden increase of internal pressure.

### 361. Estimation of the Total Protein Content in Cerebro-spinal Fluid.

G. A. YOUNG and A. E. BENNETT (*Amer. Journ. Med. Sci.*, August, 1926, p. 249) describe a short method of estimating the protein content of cerebro-spinal fluid. To 2 c.cm. of the fluid measured into an ordinary centrifuge tube, ethyl alcohol (95 per cent.) is added up to 8 c.cm.; 1 c.cm. of fluid up to 4 c.cm. with alcohol may be used where the protein content is greatly increased. The contents are then acidified with a drop of 10 per cent. acetic acid or a trace of glacial acetic acid, and heated carefully to boiling-point over a Bunsen burner. The protein immediately flocculates, and the contents of the tube are transferred to a vaccine tube with the capillary tip graduated to register 0.01, 0.02, 0.03, 0.04, and 0.05, and centrifuged until the precipitate is completely thrown down; if any collects on the side of the tube the supernatant fluid is stirred with a glass rod and the contents centrifuged again. Normal fluids contain 25 to 75 mg. per 100 c.cm. (0.005 to 0.015 c.cm. in 2 c.cm.), and border line fluids 75 to 100 mg. per 100 c.cm. (0.015 to 0.02 c.cm. in 2 c.cm.). This slight increase in total protein content is of value in distinguishing between organic and functional conditions, a positive increase favouring an organic diagnosis. The authors state that total protein determinations give one of the earliest findings of cerebro-spinal involvement in syphilis, and in neurosyphilis are valuable in estimating serological improvement under treatment. The highest readings are seen in involvement of the meninges, central neuritis, and general paresis.

### 362. Tension of the Cerebro-spinal Fluid.

P. E. NÚÑEZ (*L'Encéphale*, July-August, 1926, p. 503) states that the normal tension of the cerebro-spinal fluid, according to Claude, is below 20 in the recumbent and 30 in the sitting posture. Three degrees of hypertension may be described: the first between 20 and 40 recumbent and between 30 and 50 sitting; the second between 40 and 60 recumbent and between 50 and 70 sitting; and the third above 60 in the recumbent and above 70 in the sitting posture. Núñez records his observations on 75 cases, his conclusions being as follows. Estimation of the spinal tension without the aid of the manometer lacks any scientific and practical value. The spinal tension and the quantity of the spinal fluid are not always associated. Spinal hypertension of the second and third degree may coexist with a normal quantity of spinal fluid, and on the other hand an excess of spinal fluid may be associated with only slight spinal hypertension. A primary spinal hypertension may occur independently of any clinical manifestations in the nervous system and with a normal spinal fluid. Spinal hypertension and arterial hypertension correspond in only two-thirds of the cases. A considerable difference between the two tensions is frequent, and there is nothing to prove that spinal tension is the effect of arterial tension. In cerebral processes suggesting the presence of a tumour a differential tension between 10 and 20 is in favour of the diagnosis of cerebral tumour.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 363. Meningococcal Septicaemia.

J. C. KENNEDY (*Journ. Roy. Army Med. Corps*, July, 1926, p. 6) records four cases of meningococcal septicaemia in soldiers, aged from 19 to 25, who presented the following remarkable conditions: (1) long duration of septicaemia, in one case two years and four months; (2) the similarity of the clinical picture in all cases; (3) the presence of a rash having the characters of erythema nodosum, and suggesting that there may be a specific relation between this condition and meningococcal infection. Two of the cases terminated with meningitis, one fatally, and in both of these the blood contained a Gram-negative diplococcus, which in one case was identified as a meningococcus. The two patients who recovered had exactly similar symptoms, and from one a meningococcus Type 4 (the parameningococcus of the French) was recovered, this being the organism usually associated with the septicaemic disease in which skin, joint, and eye manifestations are frequent. The fact that the four cases all occurred in a military population, and three of them in the space of six months, is evidence that this septicaemia is more prevalent than is generally thought. As diagnosis is impossible without a blood examination Kennedy suggests that cases of meningococcal septicaemia are being mistaken for the following diseases: malaria, septicaemia, subacute bacterial endocarditis, rheumatic fever, tuberculosis, and erythema nodosum.

### 364. Haematuria following Insulin Treatment.

J. GÜDEMANN (*Wien. Klin. Woch.*, August 19th, 1926, p. 963) describes a case of haematuria following insulin treatment. The patient was a man, aged 50, who had suffered from diabetes since 1919; in six years his weight fell from 15 to 10 st. In 1923 he commenced insulin injections with definite improvement. In 1924 he had a further course of four daily insulin injections; the urine was then free from sugar and acetone. In January, 1925, the patient had severe haematuria lasting two days. No evidence of any organic disease except a quiescent apical tuberculous focus could be found. The blood pressure was 120 mm. and the urine contained erythrocytes, blood casts, and traces of sugar and acetone, though there was no evidence of any disease of the genito-urinary system. Under a strict dietetic regimen for three weeks all blood and albumin disappeared. The progress of the diabetes necessitated further insulin treatment, which was not followed by haematuria. In November, 1925, the patient showed symptoms of impending coma, and a fourth series of insulin injections was prescribed; severe haematuria followed. Although the urine was free from sugar and acetone the patient became comatose and died. At the necropsy no renal abnormality was found except a number of small punctiform submucous haemorrhages in the renal pelvis and glomerular hyperaemia. Gudemann refers to two other cases—the first in a man, aged 60, who had a severe haemorrhage from the bowel after each insulin injection; the second, a patient aged 40, with diabetes and tuberculosis, had, two months before his death, severe haematuria lasting for one week. Gudemann observes that all his own cases of haemorrhage after insulin treatment occurred in a period of four and a half years; he thinks it probable that haemorrhages after insulin treatment occur more frequently than has been believed hitherto.

### 365. Varieties of Epidemic Encephalitis.

L. BÉRIEL and A. DEVIC (*Lyon Méd.*, June 6th, p. 671, June 13th, p. 705, June 20th, p. 734, and June 27th, 1926, p. 764) refer to their previous paper on the peripheral forms of epidemic encephalitis (*Epitome*, March 28th, 1925, para. 313) and suggest the following classification of the forms of epidemic encephalitis which they have recently encountered. (1) Peripheral forms, with or without evidence of encephalitis as well. In the absence of such evidence the encephalitic nature of the peripheral neuritis, though probable, cannot be established. The authors record the case of a man affected with bilateral musculo-spiral paralysis whose wife had contracted a fatal attack of acute encephalitis two months previously. (2) Pseudo-myopathic forms, which generally, but not invariably, occur in young subjects. The affection develops progressively without any obvious infective period, being manifested by exclusively motor symptoms, and in a few months leads to a pronounced loss of muscular power. There is no obvious atrophy or anaesthesia. The condition

differs from typical myopathy by the condition being sub-acute and generally subsiding in a few weeks or months. (3) Meningeal forms. The existence of these forms has been known since the great epidemic of encephalitis of 1920, and it is probable that the cases formerly described as tuberculous meningitis with choreo-athetotic movements belonged to this group. As a general rule they end in recovery. (4) Primarily dystonic forms, with or without the usual symptoms of encephalitis. The patients in this group present acute motor disturbances which are not paralytic or ataxic, but involuntary movements consisting in a combination of muscular contractions and hypotonus which give rise to dynamic deformities, contortions, or torsion spasms. There is no atrophy, anaesthesia, or disturbance of the reflexes.

### 366. Scarletina Infection due to *Streptococcus Viridans*.

E. STENFELD (*Journ. Amer. Med. Assoc.*, July 24th, 1926, p. 241) states that during the winter 1925-26 there was an outbreak in Philadelphia of an acute infection, presumably due to *Streptococcus viridans*, which was uniformly recovered from the throat and inflammatory exudations. The onset was sudden, with headache, nausea, and vomiting. The throat was much injected, the pulse rapid out of proportion to the temperature, and moderate leucocytosis was the rule. In twenty-four to forty-eight hours an eruption appeared over the trunk and to a lesser degree on the extremities, slightly resembling that of scarlet fever. Desquamation was of a fine or furfuraceous character. Haemorrhagic nephritis frequently occurred at the time of the exanthem, or several days later. The duration of the febrile period was from one to two weeks, but longer if any complications occurred, such as peritonsillar abscess, retropharyngeal abscess, otitis media, sinusitis, or suppurative adenitis. The infection was distinguished from scarlet fever by its infectivity at all ages, which is exceptional in scarlet fever, by the atypical character of the rash, and most conclusively by the development of true scarlet fever in two cases. The prognosis was good. Scarletinal antitoxin had a favourable action, probably owing to the close biological relation of the two strains of streptococci, and possibly in part due to a non specific reaction.

## Surgery.

### 367. Non-specific Urethritis.

L. M. BEILIN (*Urol. and Cut. Rev.*, August, 1926, p. 463), who records an illustrative case of non-specific urethritis in a man due to *Micrococcus catarrhalis*, states that this condition is undoubtedly one of the most neglected subjects of the genito-urinary branch of medicine. The influence of microbes other than the gonococcus upon the genesis of urethritis was not recognized until 1883, when Boeckhart and Wolfe described pseudo-gonorrhoeal urethritis characterized by the presence of streptococci. In 100 cases of acute urethritis in his private practice Frank Kidd found gonococci in 82, staphylococci in 13, and streptococci in 5. Beilin, in 100 consecutive cases in his practice, found gonococci in 86, staphylococci in 8, streptococci in 2, *Micrococcus catarrhalis* in 1, and various unidentified bacteria in 3. Beilin's conclusions are as follows: (1) Non-specific urethritis is a definite clinical entity, which occurs more often than is generally supposed. (2) Many cases of non-specific urethritis are non-venereal in origin. (3) The exact diagnosis, especially in forensic cases, can only be made by cultural methods. (4) A patient with simple urethritis may be allowed to marry, for though he may transmit the infection to his wife, it will do her no harm. (5) Cases of simple catarrhal urethritis, while tending to spontaneous recovery, may prove exceedingly obstinate and resistant to all treatment. (6) The best plan to adopt in cases of aseptic and non-gonococcal urethritis is the avoidance of all treatment.

### 368. Treatment by Fixation Abscess.

J. CARLES (*Journ. de Méd. de Bordeaux et de Sud-Ouest*, July 10th, 1926, p. 559) relates that the method of treatment by fixation abscess, introduced by Fochier of Lyons in 1891, was at first regarded with suspicion, but subsequently was adopted with enthusiasm, especially by Bordeaux clinicians, though the Parisian school for a long time remained opposed to its use, in spite of isolated trials by Dieulafoy, Chantemesse, Rendu, and Siredey. It was not until 1920, when Netter became its advocate, that the method became widely popular

In France, in spite of the opposition of Comby, who regards it as a brutal, ineffective, and painful method, which should be consigned to oblivion. As the result of twenty-five years' experience of the method Carles comes to the following conclusions. Fixation abscesses should be employed only in exceptional cases. In mild affections they are not required, as a simpler method will effect a cure without inflicting on the patient the pain caused by their use. In severe affections the production of a fixation abscess sometimes acts like a charm, but only when an inflammatory or purulent process has to be localized, or a septic and pyaemic process needs to be cut short. Even in such cases the method must not be employed too soon or, on the other hand, too late, since it is of no use if the patient is moribund. The following technique should be employed. Oil of turpentine in a dose not exceeding 1 c.cm. is injected into the cellular tissue of the middle of the outer aspect of the thigh; another dose of 2 c.cm. should be given if there is no reaction from the first injection. A free incision should be made as late as possible (towards the sixth or eighth day), and the collection of pus freely drained. Rigorous asepsis should be maintained until cicatrization is complete.

### 333. Operative Treatment of Meningococcal Meningitis.

M. M. PIET (*Journ. Amer. Med. Assoc.*, June 12th, 1926, p. 1818), who records a case in a girl, aged 8 years, in which advanced meningococcus meningitis complicated by ventricular and spinal subarachnoid blockage was successfully treated by combined ventricular, cisternal, and lumbar puncture, remarks that the treatment of meningococcus meningitis by the lumbar route alone has given satisfactory results only in the presence of most favourable conditions—such as early diagnosis, the use of a specific serum, and low or moderate virulence of the organisms. Many patients discharged as cured are subsequently found to have a cisternal, ventricular, or cortical subarachnoid block, which had not been recognized, and therefore not treated. Puncture of the cisterna magna, the technique of which should be mastered on the cadaver, is indicated in all cases not showing satisfactory progress. Venicular puncture, either through the anterior fontanelle or, in older children, through a trephine opening, is demanded in cases with a ventricular block. Cisternal or ventricular puncture, or both, combined with the introduction of serum into the basilar cisterna or ventricles will do much towards preventing subsequent hydrocephalus, and in advanced or fulminating cases may be the means of saving life.

### 370. Hypersensitivity to Chloramine.

P. KUHR (*Zentralbl. f. Chir.*, August 7th, 1926, p. 2004) observes that solutions of chloramine (Heyden) have been so generally employed recently as disinfecting agents that it is advisable to record two cases in which it caused severe irritation. The author and his assistants adopted chloramine as the routine disinfectant for their hands, their practice being to wash the hands and forearms for five minutes; after this gauze compresses were applied, and finally the hands and forearms were washed for ten minutes with soap and water. The theatre sister acquired persistent bronchitis, which withstood all treatment; the cause of this was obscure for a long time until it was observed that when the sister was off duty the cough was relieved. When alcohol was substituted for chloramine as the routine disinfectant the cough quickly disappeared. She suffered also from severe intractable eczema of both forearms, which subsided after the discontinuance of chloramine. Kuhr also suffered from a less intractable vesicular eczema of the thumbs, index and middle fingers of both hands, which healed rapidly when the use of chloramine was discontinued.

### 371. Surgery of the Mitral Valve.

D. S. ALLEN and P. S. BARKER (*American Heart Journ.*, August, 1926, p. 693), in view of the development of a new surgical procedure for the relief of mitral stenosis, have performed a series of investigations upon etherized dogs. There are two possible avenues of approach to the mitral valve through the heart wall: (1) through the wall of the left auricle, or, more specifically, through the left auricular appendage; and (2) through the wall of the left ventricle. Since it is proposed to employ one of these approaches in surgery of the human heart, the question arises as to which of the two is the safer. The authors found that in each animal of the transventricular series the disturbance of rhythm approached too closely to ventricular fibrillation to be safe, the ventricles being thrown into fibrillar contraction by any form of irritation, mechanical or electrical. On the other hand, approach to the mitral valve through the left auricular appendage gave rise to no dangerous or even serious disturbance of rhythm. The conclusion is therefore drawn that the latter route is the safer one to use.

## Therapeutics.

### 372. Vaccine and Serum Treatment of Cerebro-spinal Fever.

COURTOIS-SUFFIT and G. GARNIER (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 8th, 1926, p. 1185) remark that cerebro-spinal fever, which formerly responded so rapidly to serum treatment, has lately been becoming increasingly refractory to this method, so that cases are often seen where injections of antimeningococcal serum have no effect on the course of the disease, even when the serum has been given in adequate and repeated doses. The authors record two cases of cerebro-spinal fever in which serum therapy proved absolutely useless and was replaced by an autogenous vaccine. In the first case rapid improvement followed and the temperature fell to normal, while the second case, in which meningococcal septicaemia was present, ended fatally in spite of the vaccine treatment. Commenting on these cases, L. MARTIN (*ibid.*, p. 1192) combats the pessimistic view held by Courtois-Suffit and Garnier as to the value of antimeningococcal serum. He remarks that cerebro-spinal fever is always a severe disease in adults, and that vaccine treatment, though it may be a useful adjunct, cannot take the place of serum therapy in this disease. Early employment of serum is, he considers, the most important factor in the success of the treatment, and explains why Ortoni had thirty-three recoveries out of thirty-five cases of cerebro-spinal fever treated by serum.

### 373. Quinine Injections in Lobar Pneumonia.

W. BERGER (*Wien. klin. Woch.*, August 19th, 1926, p. 969) reports very favourably on the treatment of pneumonia by intravenous injections of quinine hydrochloride in doses of about 7 to 10 grains; in one group of cases the disease being aborted, and in another group there was definite shortening of the course of the disease; in the majority of cases the patients made a good recovery in spite of senility and chronic alcoholism, or the occurrence of serious complications, such as nephritis, pericarditis, and diabetes. Furthermore, the favourable effects of quinine were shown by a transient or prolonged improvement of the general condition, of the circulation, by a reduction of the degree of leucocytosis, and a relief of subjective symptoms. Two patients recovered after the initial injection, given on the first and fourth days of the disease respectively. One patient, a woman aged 22, was admitted on the third day of the disease; the first injection of quinine was given immediately. The patient's general condition was very grave and there was dyspnoea and a cyanotic pallor. The characteristic rusty sputum contained numerous streptococci, pneumococci, and staphylococci, but no type predominated. On the third day a larger injection of quinine was given, and two days later a crisis occurred with fall of temperature. On the following evening the temperature rose again for twenty-four hours, but then became subnormal. The mixed injection may have diminished the effect of the quinine. In a second case, a man aged 47, the prognosis became very grave when jaundice, nephritis, and pericarditis occurred. After the second injection of 10 grains quinine hydrochloride a crisis took place. The patient recovered in spite of the serious complications. Berger records many other successes; he believes that quinine is less useful in streptococcal than in pneumococcal infections, and that the success of treatment depends largely on its early commencement.

### 374. Treatment of Constipation.

E. L. KELLOGG (*Med. Journ. and Record*, August 18th, 1926, p. 199) classifies constipation as dietetic, habit, spastic, or atonic and mechanical. Treatment may include diet, exercise, massage, electricity, abdominal support and drugs, and many cases can be best treated by a combination of several methods. In mechanical obstruction radiology should be accepted only as providing information, and should not discourage medical treatment; the advisability of surgical operation should be considered only after all other efforts have failed. Dietetic constipation is recognized by the history and the curative effect of a properly regulated diet, treatment consisting in prescribing laxative foods (fruit, green vegetables, whole-wheat bread, butter, cream, and oil) and a sufficiency of fluids. Habit constipation results from a failure to heed natural impulses, and the patient should be taught to yield promptly to the desire for a movement and to pass a morning stool regularly. Spastic constipation is due to a tonic spasm, usually of the descending colon or rectum, and is often associated with atony of the caecum and ascending colon; it is best treated by mild medication (laxatives, bland enemata, and suppositories), local sources of irritation, such as haemorrhoids and fissures, being dealt with as so. Atonic constipation may result from general asthenia or

764 C

with those of Peyser; two patients showed no departure from the normal reactions of the non-pregnant state, five showed vagotonia, and eight gave evidence equally of vagotonia and sympathicotonia. Of the twenty-three patients whose labour had been characterized by primary uterine inertia, only one gave vagotonic reactions, and three only showed the mixed vagotonic and sympathicotonic reaction, while 78 per cent. gave neutral reactions resembling those found apart from pregnancy. Four patients in this series showed clear signs of sympathicotonia, which was never noted in the puerperium of normal subjects. These results are taken to indicate that pregnancy is normally associated with variations in the vegetative nervous system, which are predominantly vagotonic. Where there is uterine inertia the sympathetic nervous system is more than usually labile, with a tendency to sympathicotonia.

### 381. The Ovarian Hormone.

B. ZONDEK (*Zentralbl. f. Gynäk.*, July 31st, 1926, p. 2050) has estimated by Allen and Doisy's method the hormone content of various portions of the human ovary; these were implanted in castrated white mice and the oestral phenomena produced were measured by examination of swabs of the vaginal secretion. He found that an oestrogenous hormone was absent from the germinal epithelium, the stroma, and the primordial follicle, almost absent from the small follicles, but abundantly present in the ripe follicles and liquor folliculi. He gives the following account of the physiology of the ovarian internal secretion. The hormone reaches the circulation by lymphogenous absorption from the peritoneal fluid which receives the discharge from the ruptured follicles, and by direct absorption from the wall of the corpus luteum. It is found there until menstruation, diminishes during menstruation, and is absent from the post-menstrual corpus luteum. Hormone production continues during pregnancy, when it is found in the corpus luteum of pregnancy, the regressing follicles, and the placenta. Zondek denies the endocrine function of special interstitial cells or glands; he maintains that the ovarian hormone, which is unique and produced in the follicular apparatus, is responsible for sexuality and the secondary anatomical sexual characters. The lipoids are not identical with the hormone. The ovarian hormone cannot be replaced by other internal secretions, but ovarian hormone production can be stimulated by other endocrines, especially that of the anterior lobe of the pituitary. S. LOEWE (*Ibid.*, p. 2051), as a result of similar quantitative experiments, concludes that the small degree of success which has hitherto attended ovarian therapy is due to the very small amount of hormone which is present in the preparations usually employed. POLL and BLOTEVOGEL (*Ibid.*, p. 2053) have enumerated the adrenalogenous (chromaffin) cells in the ganglia of Frankenhäuser, which lie in the broad ligaments at each side of the cervix. They find these cells to be five times as numerous in the pregnant as in the non-pregnant mouse, and nine times as numerous at term, after which they rapidly diminish in number. Both in the castrated and the normal animal these cells become more numerous after injection of ovarian hormone.

## Pathology.

### 332. The Pathology of Sickie-Cell Anaemia.

M. DREYFOOS (*Arch. of Pediat.*, July, 1926, p. 437), who reports an illustrative case in a negro boy, aged 3½ years, defines sickle-cell anaemia, first described by J. B. Herrick in 1910, as an hereditary and familial disease peculiar to individuals with negro blood, characterized by peculiar changes in the red corpuscles, and manifested clinically in various degrees of severity by anaemia, muscular and arthritic pains, palpitation, weakness and dyspnoea, abdominal crises, leg ulcers, and a tendency to remissions and exacerbations. The red cells vary in number from 500,000 per c.mm. in active cases to 5,000,000 in latent cases, and the haemoglobin from 15 to 65 per cent. in active, to 90 per cent. in latent cases. The colour index is usually normal and often above normal. The white cells are increased in active cases, in which they generally range between 10,000 and 20,000 per c.mm.; in latent cases there is no leucocytosis. The platelets are moderately increased in both latent and active phases, varying between 300,000 and 500,000 per c.mm. The differential count presents no abnormal characteristics. In active cases the red cells show marked poikilocytosis; a number, varying from 5 to 40 per cent., assume sickle-shaped and oat-shaped forms, which are darker and more highly refractile than the other cells. Otherwise the red cells show a marked polychromatophilia, and may present basophilic degeneration and stippling. Numerous nucleated cells of all sizes, especially normoblasts, are encountered. The blood picture changes

rapidly with fluctuations in the disease. During a relapse sickle cells may constitute 40 per cent. of the red corpuscles, but as a remission sets in they may almost entirely disappear. Anisocytosis and polychromasia persist, and some nucleated cells are always found. *Post mortem* the most important changes are encountered in the blood, spleen, and bone marrow. The red corpuscles in all the tissues show the same changes as those which have been seen during life. The spleen exhibits invasion of the reticular spaces by red cells, with evidence of active blood destruction, as shown by the large deposit of pigment; haemorrhages and infarcts are generally present. The bone marrow shows marked increase in the number of red cells, which are much deformed and in active cases nucleated. The marrow elements proper are also increased numerically. Dreyfoos thinks that sickle-cell anaemia is probably due to a primary affection of the spleen and haemopoietic organs, and must be distinguished from syphilis, tuberculosis, haemolytic jaundice, pernicious anaemia, and secondary anaemias. The prognosis is said to be good in adults, but should be guarded in children owing to susceptibility to pneumonia, tonsillitis, and other secondary infections. Treatment is symptomatic.

### 383. Bacteriology of Bronchopneumonia after Measles.

N. HENNING (*Jahrb. f. Kinderheilk.*, July, 1926, p. 217) records his bacteriological investigations in a very severe epidemic of measles in a children's home in Berlin in 1922, when 130 children were attacked, with a 30 per cent. mortality generally and a 50 per cent. death rate for children under 2 years of age. Almost all the deaths were due to bronchopneumonia, though in some cases there was associated adenitis and ulceration of the mouth and vulva. The bacteriological examinations were mostly made after death; haemolytic streptococci were cultivated from all the organs of those who had died from bronchopneumonia, the deaths being due to streptococcal septicaemia, of which the lung disease was one of the manifestations. Subsequent examination during life of 85 other cases of uncomplicated measles showed that haemolytic streptococci could never be recovered from the sputum. On the other hand, out of 25 cases of measles bronchopneumonia, 12 showed haemolytic streptococci and 4 pneumococci in all the organs, while in the rest no definite pathogenic organisms could be detected. Owing to the rapidity with which measles bronchopneumonia spreads through a ward, which explains the high mortality of the disease in hospitals, prison camps, and such institutions, Henning concludes that cases of bronchopneumonia should be isolated at once; since taking this precaution he has seen no such severe epidemic as the one reported.

### 384. Purified Diphtheria Toxoid.

A. F. WATSON and ELSIE LANGSTAFF (*Biochem. Journ.*, Vol. XX, No. 4, 1926, p. 763), stressing the desirability of purifying toxins and antigens in general, state that one of the chief difficulties in the use of the Schick test is the pseudo-reaction, due to the presence in the toxic filtrates of some substance which is more heat-stable than the specific one, and which causes rise of temperature and other non-specific reactions. A similar reacting substance appears to exist in the filtrates of the streptococcus which have been recently used in the Dick test. From their experiments, the technique of which is described, the authors come to the following conclusions: (1) The active principle of toxic filtrates of *C. diphtheriae* is confined to a very small fraction of the filtrates. (2) By formalizing the filtrates and treating them with acetic acid a highly active fraction is precipitated. (3) This active fraction can be further purified by reprecipitation methods or by dialysis, and solutions as much as a hundred times purer than the original toxoid can be obtained. Purified toxoid, like diphtheria toxoid, is a very stable substance. The purified solutions are protein in nature; they contain sulphur and occasionally phosphorus.

### 385. Origin of the Symptoms in Gastric Ulcer.

J. A. WOLFER (*Jour. Amer. Med. Assoc.*, September 4th, 1926, p. 725), as the result of the experimental production of gastric ulcers in dogs, has found that, though the ulcers resemble macroscopically and microscopically chronic peptic ulcers in man, yet there is no increase of the gastric secretion in dogs. When the ulcer was situated close to the pylorus there was a delay in the emptying time of the stomach, but when it was placed two inches away the stomach contents were evacuated in the normal time. So far as could be determined no symptoms seemed to be caused by the presence of the ulcer. Wolfer, therefore, believes that in man other factors than the ulcer itself play a part in the production of the disturbance of the gastric function and of the characteristic symptoms. He is inclined to attribute the pain and hyperacidity to mental factors, and suggests that treatment should be directed accordingly.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 356. Diet in Pernicious Anaemia.

W. F. MURPHY and G. R. MIXOT (*Boston Med. and Surg. Journ.*, August 25th, 1926, p. 410) report a distinct improvement in patients suffering from pernicious anaemia who have been given a special diet, rich in proteins, such as liver, and containing much lean meat, fruits, and vegetables, with a low percentage of fat. They recommend the following quantities: (1) Liver (calves', ox, or chicken) or lamb's kidneys freshly cooked, 4 to 6 ounces a day (cooked weight and without fat, either broiled, baked, boiled, minced, or in soup). (2) Fruit, at least 12 ounces a day—peaches and other stone fruit, pineapple, strawberries, oranges, or grape fruit; raisins to be eaten freely. (3) Lean meat, freshly cooked, at least 3½ ounces a day. (4) Not less than 9 ounces of cooked or raw vegetables—lettuce, spinach, asparagus, tomato, or cabbage. (5) Fats to be restricted to 2 ounces daily. No cheese, bacon, or fried food is allowed; very little cream or butter, and only one egg. (6) Use mineral oil for salad dressing. Sugar must be taken sparingly and all very sweet dishes avoided. (7) Starchy food and cereals to be taken sparingly; wholemeal bread, toast, or dextrinized bread, or starch. Milk should be restricted to half a pint or less, and a minimum quantity of table salt should be used. Tea and coffee may be taken as desired. All food, especially liver, should be weighed at first, after cooking, until the patient can estimate the approximate quantities of the various foods. The foods should be well cooked and made as attractive and palatable as possible. Several small meals are preferable to only three meals in the day. The above dietary may be modified to suit individual requirements—for example, in persistent diarrhoea the quantity of fruit should be reduced or omitted. Experience shows that the patient should continue to take this diet even if the red blood corpuscle count is high. The full diet should contain approximately 2,500 calories.

### 357. Mumps Meningitis without Mumps.

A. WALLGREN (*Acta Paediatrica*, August 10th, 1926, p. 53) states that, contrary to most of the other forms of meningitis, the meningitis of mumps is usually lacking in striking symptoms, and subsides rapidly and spontaneously. It is therefore easily overlooked, usually entails no unpleasant consequences, and the error is not revealed by an autopsy. In Sweden mumps meningitis is not rare, and Wallgren reports six illustrative cases from his practice. In a man, aged 27, the disease commenced with meningitis, and it was not until the third day of disease that the parotid swelling appeared. In a boy, aged 14, whose brother had parotitis complicated by meningitis, the symptoms of meningitis were associated with any parotitis or inflammation of the other salivary glands. The meningitis was of the clinical type usually found in mumps, in which the meningeal symptoms are slight or absent, whereas the cerebro-spinal fluid shows a marked mononucleosis. Similar cases of meningitis as the only symptoms of mumps have been reported by Morquio and Schoerder.

### 358. Cardiac Asthma.

J. H. PRATT (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 809) defines cardiac asthma as a paroxysmal dyspnoea, developing suddenly while the patient is at rest, accompanied by a sense of suffocation, and occurring in organic heart disease. Some attacks resemble bronchial asthma closely, even the expiratory type of dyspnoea being often mistaken for it. As the result of an analysis of 366 cases, the author defines four groups of the disease. (1) Pure cardiac asthma, which may be subdivided into mild and severe. The latter consists of agonizing attacks of suffocation, often associated with a sense of impending death, while the mild attacks are often mistaken for bronchial asthma. (2) A mixed anginous form—cardiac asthma with angina pectoris. In pure angina pectoris there is no embarrassment in breathing, and in pure cardiac asthma no pain. (3) A mixed oedematous form—cardiac asthma with pulmonary oedema. Some attacks of cardiac asthma end in pulmonary oedema, and there is evidently a close relation between the two conditions. (4) The combined form—cardiac asthma with both angina pectoris and pulmonary oedema. The attacks are characterized by urgent dyspnoea with a feeling of intense suffocation, cyanosis of the face, profuse sweating, cold skin, and a marked elevation of the blood pressure; they have an average duration of one hour. Cardiac asthma occurred

most often between the ages of 60 and 70, and this strongly suggests a causal relation of arterio-sclerosis to the symptom-complex. It is more common in men than in women, and its relation to angina pectoris seems undoubted, though many patients had no pain in the attacks of paroxysmal dyspnoea. The blood pressure is always increased, but in no case was there any disturbance of renal function, and nocturnal paroxysmal dyspnoea is not a uraemic manifestation. In most cases the heart was dilated to the left and there were signs of cardiac weakness. Little is known regarding the pathology, but it is evident that cardiac asthma is closely related to arterio-sclerosis, syphilitic aortitis, angina pectoris, and aortic insufficiency. Krehl and many others attribute the attacks to a sudden temporary failure of the contractile power of the left ventricle. Pratt does not consider this the sole cause, and believes that nervous influences and vasomotor disturbances in the peripheral circulation also are concerned. The prognosis is extremely grave, most patients dying in two, and some even in one, years after the first attack. Benefit in attacks has been obtained from glyceryl trinitrate, amyl nitrite, caffeine sodiobenzoate, and epinephrin, though the use of the last drug is attended with some danger. Morphine (1/4 grain) injected subcutaneously is by far the best remedy for a severe attack. This should be followed, if the patient has not had digitalis for four or five days, by strophanthin (1/120 grain) intravenously. Bandaging the limbs shortens the paroxysm, and bleeding (15 to 25 oz.) is recommended if life is threatened. The patient should be kept strictly in bed for six to eight weeks or longer, and continued digitalization is of possible value in the prevention of recurrence.

### 359. Typhoid Fever in the Inoculated.

ACCORDING TO F. W. SCHEMBRA (*Münch. med. Woch.*, August 20th, 1926, p. 1397), during an epidemic of typhoid fever at Anklam in the summer of 1925, 15,000 persons voluntarily submitted to inoculation. Typhoid fever subsequently developed in 70 cases, 24 of which had been inoculated once, 18 twice, and 28 three times. In most cases, however, the disease ran a mild and short course, only 3 of the cases being fatal—a mortality of 13.6 per cent. compared with a mortality of 13.6 per cent. in the un inoculated cases. Only in exceptional cases was not recognized at first was the course of the illness slow. A more or less typical tongue was present in all but 5 of the 70 cases. Rose spots were also evident in the majority of cases. The spleen was distinctly palpable in 77 per cent. In 17 cases (24.3 per cent.) bronchitis was present. The diazo reaction was usually negative. Relapses occurred in only 4.18 per cent. Most of the patients were women or youths, whereas only 6 of the men who had been inoculated during the war contracted the disease.

## Surgery.

### 359. Treatment of Chronic Mastitis.

A. J. GRANT (*Canadian Med. Assoc. Journ.*, September, 1926, p. 1054) observes that many cases of chronic mastitis will respond to simple medical measures, and that operative treatment is only justified when one or more tumour masses are palpable. It has been shown that the condition is manifested by dilatation of the ducts and acini with accumulation in them of the products of epithelial activity, the mouths of the ducts being blocked by the keratinized epithelial plugs normally present in the non-lactating breast. Though often associated with carcinoma, there is no proof, he adds, that this condition is pre-cancerous. Surgical operation is advocated in advanced cases, but in the earlier stages an endeavour should be made to free the ducts of the epithelial plugs. Localized excision is advised if a definite, permanent, benign tumour is palpable, the radical operation being reserved for carcinomatous tumours and cases in which the diagnosis is uncertain. Grant believes that there has been too great a tendency to perform mastectomy for chronic mastitis, whereas it should be reserved for cases presenting multiple definite masses, and then only when the condition is progressive. When no definite tumour mass is present the patient's pain and fears are often much relieved by the assurance that cancer is not present. In the author's experience treatment with massage and olive oil, followed by the application of wet boric dressings to the nipple, has given good results.

**391. The Surgical Treatment of Gastric Spasm.**

E. CRONE-MÜNZEBOCK (*Zentralbl. f. Chir.*, September 18th, 1926, p. 2333) recommends digital dilatation as being safer than any form of instrumental treatment of spasm of the cardiac orifice of the stomach. His first patient, aged 53, had been ill for twenty-three years, and during the last ten years had become extremely emaciated. On opening the abdomen the author found a hard hypertrophied muscular ring, of two fingerbreadths, at the lower end of the oesophagus. He opened the stomach and introduced three fingers into this ring, dilating it until the circumference was increased to 13 to 14 cm. The result was good. Four years after the operation the patient was free from pain and had gained 34 lb. in weight. A barium test meal containing breadcrumbs was seen to pass easily through the cardiac orifice when the patient was examined through the fluorescent screen. The second patient, a man aged 42, had suffered for ten years from severe dysphagia. The condition found at operation led the author to decide that internal dilatation in this case would be safer and simpler than a plastic operation. The result was very satisfactory. Six weeks after the operation the patient had gained 24 lb. The author remarks that when digital dilatation is performed, the fingers must not be withdrawn for ten or fifteen minutes and the circumference of the dilated cardia should be not less than 13 or 14 cm.

**392. Investigation of the Interior of Joints.**

As an alternative to the practice of arthroscopy for the purpose of examining the interior of a joint, E. S. GEIST (*Journal-Lancet*, July 1st, 1926) suggests the use of an apparatus comparable with the otoscope or urethroscope, which permits examination of the interior of a joint cavity, and also the removal of tissue for pathological examination. He has conducted experiments successfully on the dead body, using a simple otoscope modified by lengthening the tube. With the aid of a stylius this instrument was inserted like a trocar into the joint. Geist found that it was possible to study the greater part of the articular surfaces, portions of the semilunar cartilages, a considerable extent of the synovial surface of the joint proper, and of the suprapatellar bursa. He suggests that with the use of local anaesthesia arthroscopy can be performed with little more distress to the patient than would be caused by a simple aspiration, and that the operation of arthrotomy could thus be obviated in many cases.

**393. Unsuccessful Appendicectomies.**

KELLING (*Münch. med. Woch.*, September 24th, 1926, p. 1610) states that it is a well known fact that very many appendicectomies are failures, the patients continuing to complain of the same symptoms as before the operation. It is obvious that in such cases the pain has not been caused by appendicitis, but by other conditions, such as catarrh of the large intestine, adhesions, oxyuriasis, salpingitis, ureteral calculus, neuralgia, floating kidney, typhlophobia, or gall stones. Persistence of symptoms after appendicectomy is chiefly found in weakly asthenic girls or males with a long narrow thorax, usually between the age of 15 and 30, as well as in thin persons who have to keep much upon their feet. The symptoms disappear after prolonged rest in the recumbent position, and may be cured by wearing a suitable bandage or by a generous diet which causes a deposit of fat in the abdominal wall.

**394. Bilid Ureter with Partial Hydronephrosis.**

C. COLUCCI (*Il Policlinico*, Sez. Chir., September 15th, 1926, p. 447) reports a case of partial hydronephrosis with double ureter in a woman aged 30. For the previous six years she had suffered from attacks of renal colic, with lumbar pain and vomiting, but there was no fever, no diuresis after the pain, and no haematuria. Later on a swelling was noticed in the right loin, which almost disappeared after the colic ceased. Pyelography showed deformation of the renal pelvis and curvature of the ureter, but no evidence of double ureter. The kidney was mobile. At operation the kidney was found partially hydronephrotic and was removed. It was then seen that the ureter was bifid, and after the junction of its upper divisions the single tube passed below the iliac vessels. The author suggests that if the ureteral catheter had been inserted further some evidence of bifurcation might have been obtained. By passing the catheter a short or a long distance up the ureter different types of urine might have been noted which would help in the diagnosis. Uretero-pyelography, with the catheter only passed a short distance, might have revealed the bifid condition. The partial hydronephrosis may have been due to a rather sharp-angled position of the ureteric opening in the bladder associated with mobility of the kidney. The author discusses the question of partial or total nephrectomy in these cases, and gives a photograph of the excised kidney and ureter which demonstrates the condition found. A short bibliography is appended.

**Therapeutics.****395. Phenylhydrazine in Erythraemia.**

G. E. BROWN and H. Z. GIFFIN (*Arch. Intern. Med.*, September 15th, 1926, p. 321) discuss the treatment of polycythaemia vera (erythraemia) with phenylhydrazine. Experiments on animals have shown that the drug has a specific effect in the destruction of erythrocytes. Details are given of seven patients so treated; the effect of the drug on the destruction of blood and the reduction of erythrocytes was found to be definite, constant, specific, and symptomatic of a haemolytic crisis. Small doses caused an increase in leucocytes, but the platelet count was unaffected. The effect of the drug continued for seven to ten days after its discontinuance. There was a marked reduction in the volume of the blood directly proportional to the destruction of the erythrocytes, and when anaemia had been produced a relative increase in the plasma volume was noted. Jaundice, accompanied by an increase in the serum bilirubin, appeared early; there was a marked rise in the blood urea and a slight increase of the creatinine. All but one patient improved clinically, the vertigo, fullness of the head, neuralgia, mental irritability, and pains in the legs disappearing. When this last symptom is apparently due to calcification of the arteries it is suggested that the drug might prove beneficial in endarteritis obliterans without polycythaemia. Doses of 0.10 gram were given three times a day, it being estimated that each gram of phenylhydrazine destroyed an average of 6 grams of haemoglobin; the drug should be discontinued when the erythrocyte count drops to 4,500,000 per c.mm., since destruction continues for about a week afterwards. The authors consider that phenylhydrazine causes more consistent improvement in symptoms and more constant reduction in blood volume than either radiotherapy or venesection, and that the problems of the possibility of thrombosis, and the ultimate toxicity of the drug, especially for the liver, require further investigation.

**396. Serum Therapy in Scarlet Fever.**

S. S. WOODY (*Therapeutic Gazette*, July 15th, 1926, p. 477) reports the successful employment of passive temporary immunization in 97 Dick-positive cases after varying degrees of exposure to infection. Serum was obtained from five different manufacturers, and in each instance one injection was given forty-eight hours after exposure to infection. Up to the age of 3 enough antitoxin to neutralize 50,000 skin test doses was given; from 4 to 6 the dose was equivalent to 75,000 skin test doses, and over 6 to 103,000. All the patients gave a Dick-negative reaction seventy-two hours after injection, and not one of them developed scarlet fever during a stay in hospital ranging from four to sixteen days. No control tests were made in this series for duration of immunity. In another series 75 patients admitted to hospital owing to erroneous diagnosis and exposed to infection from scarlet fever in the ambulance or the wards for periods up to sixteen days were given the serum equivalent of 100,000 skin test doses and all escaped the disease. The author considers that this experience justifies the use of the antitoxin in cases of family and hospital exposure. In the treatment of the actual disease by antitoxin, on the same lines as in diphtheria, Woody quotes 160 severe cases so treated with very good results as compared with untreated cases. He claims that the treatment results in a quicker subsidence of toxæmia, more rapid fading of rash, swifter recovery of the mucous membranes, and a reduction in the number of carrier and return cases. The dose of antitoxin varied from 250,000 to 700,000 skin test units according to the patient's age and the severity of the disease. He emphasizes the importance of the throat symptoms as indicating the severity of the disease. Serum reactions were a little more severe than with diphtheria antitoxin, but did not appear in more than 11 per cent. of those injected.

**397. Digitalis Therapy in Children.**

A. W. JACOBSEN and W. C. DAVISON (*Amer. Journ. Dis. Child.*, September, 1926, p. 373) consider that the common ineffectiveness of digitalis in the treatment of cardiac disease in children is due to the fact that the doses used have been too small. In their experience the administration of comparatively large doses of digitalis to oedematous children suffering from rheumatic heart disease usually causes a loss of oedema, an increase in the patient's comfort, and prolongation of life. The dosage they recommend for children suffering from failure of cardiac compensation is 3 grains of the dried leaves of digitalis, given by the mouth in capsules every six hours until nausea develops—usually after four to eight doses. The dose should then be decreased to  $1\frac{1}{2}$  grains of the dried leaves twice a day, to replace the amount which the patient excretes daily. This treatment may, they add, usually be continued indefinitely. Should such symptoms of intoxication as nausea

or marked slowing of the pulse develop on this reduced dosage, digitalis should be discontinued and not readministered until one or two days after all symptoms of intoxication have disappeared. For patients who have been vomiting before digitalis therapy is begun, 30 minims of the tincture of digitalis diluted with 1 ounce of normal saline may be given by the rectum every six hours until the pulse rate is reduced—usually after four to eight doses. The amount should then be reduced to 15 minims, diluted with 1 ounce of normal saline, and be given twice a day.

### 338. Vaccine Treatment of Whooping-cough.

A. H. KRIJGER (*Nederl. Tijdschr. v. Geneesk.*, September 11th, 1926, p. 1176) has treated 52 cases of whooping-cough with pettus-*is* vaccine at the Utrecht Children's Polyclinic. The doses used were 2,000, 3,000, 5,000, and 5,500 organisms with two days' interval between each injection. This dosage was used for children of all ages, including infants, in whom the treatment was most successful. In some cases a final injection of 5,000, or even of 7,500, organisms was given after a week. The cases were divided into three groups according to the results: (1) 22 cases in which the results were very good; (2) 11 cases in which the results were not so striking but were still satisfactory; and (3) 19 cases in which the vaccine had no effect. Local reaction in the form of a painful red infiltration at the site of injection associated with a general reaction manifested by malaise and rise of temperature was noted in 14 cases; it was remarkable that 12 of the cases belonged to the first two groups. The results were not any better when the vaccine was used early, and even when it was injected at a late stage it was frequently effective.

## Radiology.

### 339. Radiological Examination of the Uterus.

G. U. NEWELL (*Amer. Journ. of Obstet. and Gynecol.*, August, 1926, p. 183) records his experience of the injection, for diagnostic purposes, of 40 per cent. iodine solution in vegetable oil (iodipin) into the uterus, with subsequent x-ray examination. In 38 cases he has seen no untoward results follow. The amount injected, slowly and gently, was 7 c.c.m.; screening was performed at once, and the patient returned home. The oil disappears from the abdomen more quickly than from the spinal canal, and has been found to be absent fourteen days after uterine injection, although in one patient it was still present in small amounts in the pelvis sixty days later. Newell finds this procedure particularly valuable (1) in sterility cases with tubal obstruction, to localize the obstruction and determine whether an operation is likely to be useful; (2) when several masses are palpable within the pelvis, so that the uterus can be distinguished from the others; (3) when the pelvis is blocked by one large mass, and it is doubtful whether this originates from ovary or uterus; (4) when intrauterine or extrauterine foreign bodies are suspected; (5) as an indication of the size of the uterus and a possible encroachment on its cavity by tumour. The iodine injections may also help in the differential diagnosis of chronic appendicitis from right-sided salpingitis, and of tuberculosis from infective salpingitis. Of Newell's patients thirty came later to laparotomy.

400. G. COTTE and P. BERTRAND (*La Gynecol.*, June, 1926, p. 353) prefer radiographic examination after injection of an oily iodine solution to examination by Rubin's insufflation method. They have not noted subsequent secondary infection or salpingitis, as has been reported after that procedure. They state that before and after the iodine injections the patient should be observed in hospital. If there is obstruction at the uterine ostia of the Fallopian tubes the oil does not leave the uterus; if at the abdominal ostium, the ampulla still contains oil at the end of twenty-four hours. If the tube is permeable little oil remains there, the bulk being found in the pelvic cavity. Radiographic examination after oily injections of iodine is a valuable preliminary to operations for dysmenorrhoea or sterility, and in patients in whom salpingectomy or salpingostomy has previously been performed.

### 401. Radiological Diagnosis of Chronic Sinusitis.

P. B. MACCREADY (*Boston Med. and Surg. Journ.*, September 2nd, 1926, p. 464) advocates the use of iodized oil as an opaque medium in the radiological diagnosis of chronic sinusitis and maxillary cysts. A thorough irrigation of the antrum or frontal and sphenoidal sinuses with sterile saline solution is first performed to wash out any free pus; the solution is carefully removed and 5 c.c.m. of 10 per cent. iodipin is injected, a stereoscopic x-ray view being taken as soon as possible afterwards. MacCreedy states that, though the ethmoid sinuses cannot be injected, much can be learned

from the course of the iodized oil as it passes into the nasopharynx, since normally the cilia carry it back in definite currents. In chronic sinusitis thickening of the mucous membrane, with the frequent formation of small abscesses or a polypoid degeneration, results, and this thickening of the lining membrane of the sinuses is readily demonstrated by x-rays after injecting iodized oil. In obscure cases where changes have been produced long after all sinus symptoms have subsided, this method, by demonstrating a thickening only amenable to operation, may save the patient the discomfort of those useless repeated irrigations which in the absence of x-ray diagnosis are usually employed before surgical intervention. The author adds that the treatment of chronic frontal sinusitis differs from that for chronic antrum infection because many frontal sinus cases clear up with the establishment of drainage; iodized oil should be reserved for those which do not so respond. The oil is removed from the sinuses too rapidly to be of much use therapeutically, and while the removal from the antrum may take twenty-four hours it is much quicker from the frontal sinus. Little discomfort follows the injection, though there may be a feeling of congestion in the cervical glands owing to a small amount of the oil being absorbed by the lymphatics.

### 402. Radiotherapy in Cancer of the Cervix.

W. FÜRST (*Zentralbl. f. Gynäk.*, July 24th, 1926, p. 1938) states that at the Zürich University clinic x-ray treatment is given in every case of carcinoma of the cervix uteri as soon as the clinical diagnosis has been confirmed by biopsy. From three to six weeks later the abdomen is opened and the operability of the case is estimated with the pelvic tissues exposed to view and to internal palpation. Whenever it is possible Wertheim's operation is done; in inoperable cases after-treatment is given first by radium and then by x-rays. Subsequent treatment in cases in which it has been possible to do extended (Wertheim) hysterectomy is guided by histological criteria. The margins of the excised tissue are microscopically examined; if it is found that excision has been made through malignant tissue, x-ray treatment is begun at once, a small series of applications separate by considerable intervals being preferred. If, on the other hand, the ablation appears to have been made through healthy tissue, x-ray treatment is only given if a recurrence of the growth becomes manifest later. Fürst believes that x-ray and radium treatments, although indispensable accessories, do not possess so great a value in treatment of cancer of the cervix as was formerly hoped. He has found by inquiry that of thirty-six Swiss and German university clinics only six adopt radiotherapy exclusively. Among the advantages claimed for preliminary treatment of all cases of carcinoma of the cervix by x-rays are that in cases afterwards operated on, suppuration and inflammation around the tumour are diminished, and that in inoperable cases the shrinkage of the tumour after x-ray application enhances the effect of radium therapy. F. HEIMANN (*ibid.*, p. 1945), on the other hand, while conceding that the disappearance of suppuration and the epithelialization of the portio cervicis which follow x-ray treatment of cervical carcinoma may be of great benefit, asserts that streptococci, if locally present before this treatment, are invariably to be found afterwards. An equally efficient diminution of local sepsis may be secured, he finds, by cautery excision and application of 5 per cent. alcoholic solutions of thymol. In this way can be avoided the delay of several weeks before operation, during which the neoplastic permeation may extend.

## Obstetrics and Gynaecology.

### 403. Malignant Melanoma of the Vulva.

J. L. GOFORTH (*Surg., Gynecol. and Obstet.*, September, 1926, p. 322), who records three illustrative cases of malignant melanoma of the vulva in women aged 36, 66, and 56 respectively, all arising primarily from the labium majus, states that his studies, like those of others, indicate that the melanomata are of epithelial origin. He urges that vulva pigmented naevi should be regarded as being potentially malignant, and should be treated by excision with a wide margin of apparently healthy tissue in all directions. Pigmented spots or moles about the vulva are particularly subject to the influence of climate, irritation, inflammation, and trauma—factors which are instrumental in inducing a malignant change. The proper treatment for cases in which malignancy is well established or in which recurrence exists consists in a radical removal of the growth, together with the regional lymphatic area. The patient should subsequently be kept under observation, so that she may have the advantage of the earliest treatment of a local recurrence.

402. **Obstetrical Tears of the Perineum and Vagina.**

G. SERDUKOFF (*Gynecol. et Obstet.*, 1926, xiv, 1, p. 29) finds that rupture of the perineum during labour occurs, according to older reports, in from 6 to 10 per cent. of cases, and according to more recent investigations in 11 to 30 per cent. at least; it is said to be more common in blondes. Systematic median episiotomy in the author's clinic appears to have diminished foetal mortality by 1.5 per cent. and to be followed by a high percentage of healing by first intention. He prefers, however, to inject oil of white vaseline, in imitation of the lubrication naturally afforded by the vernix caseosa. The oil, which has been sterilized by at least three successive boilings, is injected to the amount of 50 to 60 grams, between the head and posterior vaginal wall, at a time when the presenting part is visible at the vulva during the pains but disappears between them. Comparing a series of 2,000 labours in which oil was injected with one of 350 in which it was not used, Serdukoff found vulvo-vaginal fissures in 6 per cent. of the former as compared with 14 per cent. of the latter, and ruptures of the perineum in 10 per cent. and 15 per cent. respectively.

405. **The Toxaemias of Pregnancy.**

J. HOFBAUER (*Amer. Journ. Obstet. and Gynecol.*, August, 1926, p. 159) records successful attempts to reproduce experimentally in animals the characteristic clinical symptoms and the microscopical and chemical features of the toxæmias of pregnancy—premature separation of the placenta, pernicious vomiting, and eclampsia. The agent employed was histamine, and from the results obtained it is suggested tentatively that this or allied bodies may be the toxic substances concerned in the toxæmias of pregnancy. In a first series of experiments pregnant guinea-pigs received intracardiac injection of 0.25 to 1 c.c.m. of histamine in 1 in 1,000 solution per kilo of body weight. A considerable degree of placental detachment was invariably produced as a result of haemorrhages at its base, and the capillaries and veins of the entire genital tract were found to become strikingly dilated. In cats and dogs intravenous histamine injections led to tetanic contraction of the uterus with enormous engorgement of the blood vessels of the uterus and in its neighbourhood, and production of purplish petechiae in the uterus, spleen, and pancreas. Oedema of the uterine wall, and peripheral liver necroses of the anaemic and haemorrhagic types, were noted, associated with thrombi in the vessels and degenerative changes in the convoluted tubes of the kidney. The hepatic changes are described as being identical with those characteristic of eclampsia; it is noted also that, as in eclampsia, the histamine injections were followed by intracellular precipitation of bile, and that, as in hyperemesis gravidarum, there was a great diminution in hepatic glycogen after histamine injections. In a preliminary report the statement is made by Hofbauer and Geiling that when insulin is repeatedly injected together with histamine the normal conditions of the liver and kidney are maintained. Hofbauer admits that it is impossible to draw the conclusion that histamine or similar substances are the actual toxic substances of pregnancy toxæmias, until they have been demonstrated in the blood; here, however, detection of small amounts is exceedingly difficult. One difficulty in the way of accepting histamine as the pregnancy toxin is that its effects include a drop in the blood pressure, while eclampsia is associated with hyperpæsis; there is some evidence, however, that histamine stimulates adrenaline production. Experimental findings are reported which show that both in eclampsia and histamine poisoning there is hyperglycaemia, together with increases in the uric acid, inorganic phosphates, and lactic acid in the blood. With regard to treatment, Hofbauer advises strongly against chloroform or ether as an anaesthetic in operations for premature placental detachment or eclampsia, and advocates administration of nitrous oxide with abundant quantities of oxygen. In placental detachment transfusion of blood and administration of glucose are important forms of treatment.

## Pathology.

406. **Bactericidal Powers of the Digestive Secretions.**

K. MYLIUS and F. SARTORIUS (*Centralbl. f. Bakt.*, September 20th, 1926, p. 565) have made some experiments to determine the effect of the gastric and pancreatic juices on a number of common bacteria. Previous work showed that the gastric juice caused a granular degeneration of tubercle bacilli, but that duodenal secretions had no effect. In their present experiments they used the intestinal secretions of the dog, recovering them from the stomach or duodenum by a fistula. In some instances the fluid was used in the unfiltered condi-

tion; in others it was passed through a Berkefeld candle just before use. To 1 c.c.m. of intestinal juice were added 5 drops of a bacterial suspension made by washing off an eighteen-hour agar slope culture in 3 c.c.m. of salt solution. Immediately afterwards, and at intervals of two, four, and twenty-four hours, subcultures were taken to ascertain the viability of the organisms. The bacteria used were staphylococci, hay bacilli, and three members of the typhoid-dysentery group. On *B. subtilis* neither the gastric nor the duodenal fluids had any effect; on the other organisms the effect of the gastric juice was to sterilize the suspension in under two hours. The duodenal secretion had little or no action; good growths were obtained in each instance after twenty-four hours. The effect of adding duodenal fluid half an hour after a mixture of gastric juice and bacterial suspension had been prepared was to diminish the activity of the mixture; instead of a complete sterilization in two hours, as was accomplished by gastric juice alone, the organisms were not killed for about four hours or even longer. These experiments, therefore, show that in the case of the dog the gastric juice has a strong bactericidal effect on non-sporing bacteria, whereas the duodenal juice has little or no such effect. They attribute the bactericidal power of the gastric juice entirely to its acid content and believe that pepsin has no such action.

407. **Ligneous Thyroiditis.**

L. W. SMITH and H. M. CLUTE (*Amer. Journ. Med. Sci.*, September, 1926, p. 403) report five cases of chronic ligneous thyroiditis (Riedel's struma) occurring in women aged between 49 and 67. In three the clinical picture suggested malignancy, while the other two patients were non-toxic; all recovered after surgical removal of the growth. In two cases there was extracapsular extension of the growth, but in the other three it was well encapsulated. The salient points in the pathology are an extensive and diffuse infiltration, and replacement of the normal thyroid tissue by lymphocytes, atrophy of the acini, and abortive attempts at glandular hyperplasia in early cases. The acinar epithelium later undergoes metaplasia, with the formation of large cuboidal cells containing a greatly increased amount of eosinophilic cytoplasm. Fusion of the cells occurs, their nuclei remaining apparently viable and so suggesting giant-cell formation. Later, connective tissues replace the glandular structures, and, finally, an almost solid mass of connective tissue is left, with foci of lymphocytes and occasional acini. Although the etiology is believed to be bacterial, no evidence of infection was obtained in any of the five cases, cultures on various media being always negative and animal inoculation causing no symptoms.

408. **The Mechanism of Recovery from Insulin Convulsions.**

L. B. WINTER (*Biochem. Journ.*, vol. xx, No. 4, 1926, p. 668) cites the discovery by Winter and Smith that glycogen is present in apparently adequate amounts in the liver and muscles of an animal which has had the blood sugar reduced to the convulsion level as a result of insulin injection. Cori found that, while the sugar in the liver was decreased, that in the muscles and brain was not appreciably affected; according to Barbara E. and E. G. Holmes (*Epitome*, August 15th, 1925, para. 115) examination of the reducing substances in the brain showed that there was little or no glucose present. These two workers suggested that the brain might suffer from glucose starvation during insulin convulsions, for since the reducing substance of the brain was not glucose, the brain must depend for its sugar on the glucose level of the blood which flowed through it. Winter found that a rabbit at the moment of insulin convulsions, or even one hour afterwards, had as much reducing sugar in the liver and muscles as had a normal rabbit, and that recovery was brought about by the injection of some agent antagonistic to insulin, such as adrenaline, glucose, mannose, glucosan, or glucal (an unsaturated reduction product of glucose). He thinks that the recovery due to adrenaline can be explained on the lines of antagonism between one internal secretion and another, but that this does not explain the action of glucose. He suggests that only a small part of the glucose injected is available for the immediate needs of the body, and that the rest is seized upon for conversion into glycogen. Winter found that the minimum amount of sugar necessary to restore a rabbit weighing approximately one kilogram was half a gram. He adds that the amount of sugar necessary for recovery, taking into account the reducing sugar already in the tissues, makes it probable that much of it is rapidly converted into glycogen until the excess of insulin is countered, and that after this the metabolism of carbohydrate can proceed normally. The recovery from convulsions by means of glucal is not surprising in view of its reactivity and the ease with which it can be converted into mannose and possibly glucose.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 409. Immunization against Scarlet Fever.

H. S. DIEHL (*Minnesota Med.*, September, 1926, p. 518) states that during the last three years Schlick tests were performed on 8,063 students aged from 15 to 25 and over on entry to the University of Minnesota; 5,183 were females and 2,905 males. Of the total 52 per cent. were positive. There was very little difference in the percentage of susceptibles in these age-groups, but a tendency to slight increase from 16 to 21 years was noted. The percentage of positive reactions was slightly higher among the girls (54) than among the boys (51). There was a somewhat greater amount of susceptibility among students from the smaller communities than from the larger. Owing to the large number of susceptible persons discovered, Diehl suggests that in dealing with children of school age or under it would be better to give all of them toxin-antitoxin inoculations than to inoculate only those shown to be susceptible by a previous Schlick test.

410. J. T. BOKAY (*Deut. med. Woch.*, July 15th, 1926, p. 1250) records observations on 4,344 Dick tests performed in Budapest, of which 1,774, or 40 per cent., were positive and 2,538, or 60 per cent., were negative. Of 66 newborn children the reaction was negative in 62 and positive in 4. Prophylactic injections with scarlet fever toxin were made intramuscularly in the deltoid and the gluteal regions, four being given weekly or every five days, the total dosage ranging from 2,500 to 7,500 skin test doses. Bokay agrees that there is a close connexion between the result of the reaction and susceptibility for scarlet fever. The skin reaction is free from danger, but reliable toxin solution must be used and the technique be exact. He finds that active immunization by methodical injections of toxin causes the skin reaction to become negative in most cases. A further careful collection and study of cases is needed to explain certain questions of detail, such as duration of immunity. The procedure is free from risk in the hands of a trained practitioner who employs a reliable solution of toxin and suitable dosage. He adds that the toxic erythemas which occasionally appear have no special significance and run a mild course.

411. S. S. WOOLY (*Therap. Gaz.*, July 15th, 1926, p. 477) states that passive immunization against scarlet fever has proved satisfactory in 97 cases after varying degrees of exposure. Preparations from five different manufacturers were used and the serum was given in one injection forty-eight hours after exposure. In children up to 3 years of age antitoxin to neutralize 50,000 skin test doses of toxin was used; from the fourth to the sixth years 75,000 skin test doses, and to all over 6 years 100,000 skin test doses. All the patients gave a negative Dick test when retested seventy-two hours after the administration of antitoxin, and not one developed scarlet fever during an average of from four to sixteen days' subsequent stay in hospital. In more than 75 additional cases exposed to scarlet fever, but with negative scarlet fever histories, antitoxin to neutralize 100,000 or more skin test doses was given, and not one developed the disease in spite of direct and intimate association with active scarlet fever cases in the acute wards. Wooly concludes that antitoxin may be recommended as an emergency prophylactic measure in families, and more particularly in hospitals and other institutions where scarlet fever may develop.

412. For the immunization test in scarlet fever H. S. SNYDERMAN (*Med. Journ. and Record*, September 15th, 1926, p. 332) has been using intracutaneous injections of the soluble toxic filtrate diluted from 1 in 500 and 1 in 2,000 in physiological sodium chloride solution. He finds that a local effect begins to appear from four to six hours after inoculation as a small circular area of erythema, increasing in size and reaching a maximum between eighteen and thirty-six hours. Of 1,467 children tested in institutions 31 per cent. gave a positive reaction, while of 156 tested in private practice the reaction was positive in 66 per cent. All those children with a positive reaction were given four injections of scarlet fever toxin at weekly intervals for immunization. The local reaction consisted of redness and swelling at the site of the injection about thirty-six hours later, the first injection producing the severest reaction. Snyderman considers the test to be a reliable index of determining the susceptibility or immunity to scarlet fever and the efficiency of active immunization. Immunity is produced within a fortnight

after the last injection, but is not permanent; he finds that a single injection of a large dose will produce an early and more lasting immunity. He regards it as a valuable preventive agent during an epidemic, as an immunity continuing for at least six months is produced.

### 413. Post-encephalitic Obesity.

T. G. WALSH (*Journ. Amer. Med. Assoc.*, July 31st, 1926, p. 305), who records four illustrative cases, three of which were in females, aged 15, 16, and 22, and one in a boy aged 16, states that a rapid increase of weight is not uncommon among the sequels or chronic manifestations of epidemic encephalitis. Out of 89 cases of this disease reported by Grosman 15, or about 17 per cent., showed an increase of weight ranging from 15 to 95 lb. In 8 per cent. of Duncan's cases this increase was so marked that the patients complained of it. Usually the obesity is of general distribution, although it may be of the pituitary type, involving chiefly the glial region and the proximal parts of the extremities. Among other symptoms which in the absence of pituitary tumour are suggestive of post-encephalitic obesity are somnolence, narcolepsy, psychic changes, a labile temperature with occasional febrile periods, rapid fluctuations in weight with normal or raised basal metabolism, and the association of neurological symptoms. The etiological relation between rapid increase of weight and acute encephalitic disturbance has been confirmed by experiments on dogs, which have shown that obesity develops after a localized traumatic encephalitis of the mid-brain, which is the site of election of the typical pathological changes of epidemic encephalitis. Walsh recommends that in cases of rapidly developing obesity the history should be carefully studied to determine a possible encephalitic basis before the obesity is attributed to a simple functional endocrinopathy.

### 414. Permanent Non-Paroxysmal Acro-Cyanosis.

L. GALLAVARDIN and P. P. RAVAUULT (*Lyon Med.*, July 4th, 1926, p. 3) describe a syndrome which is distinct from Raynaud's disease, although it resembles that condition in the occurrence of gangrene of the extremities; it can also be distinguished from erythromelalgia, the latter being characterized by the deep red colour of the skin and increased pulsation of the arteries during the painful paroxysms. The authors describe the case of a man, aged 62, who had suffered from circulatory disturbances of the extremities since childhood. His hands were cyanosed, his nose was blue, and he was subject to chilblains. There had never been any paroxysmal phase, nor evidence of paleness of the skin. Eight years before there had been slight gangrene of the terminal joint of the right index finger; the necrotic tissue separated and the wound cicatrized, but later gangrene of the same finger recurred and the finger was amputated. The patient had complete cardiac arrhythmia with hypertrophy. The systolic blood pressure was 160 mm.; the Wassermann reaction was negative, and there was no sign of syphilis. Histological examination showed apparently normal arterial walls, but the lumen of every artery was blocked by connective-hyaline tissue perforated centrally by a minute artery. One section showed an arteriole in process of development in the hyaline thrombotic mass. These lesions were limited to the arteries; the veins were everywhere normal. The patient was not of Jewish descent; the primary lesion was not an ordinary obliterating endarteritis and there was no evidence of Raynaud's disease. The authors are uncertain whether the arterial lesions were the result of the gangrene or the exciting cause of it and of the preceding vasomotor disturbances.

### 415. Erythema Nodosum and Tuberculosis.

T. BYDAL (*Norsk Mag. for Lægevid.*, August, 1926, p. 675) records observations on 39 cases of erythema nodosum (33 in females and 6 in males), in 16 (41 per cent.) of which, after an interval ranging from a few days to several years, symptoms of tuberculosis developed, especially pleurisy and pulmonary disease. Another 6 cases (15.4 per cent.) showed symptoms suggestive of tuberculosis, so that there was a total of 22 patients (56.4 per cent.) in whom erythema nodosum was followed by evidence of tuberculosis. Bydal therefore concludes that erythema nodosum is a considerable number of cases may herald the onset of tuberculosis, and recommends that patients with erythema nodosum should be kept under observation as long as possible after their attack, especially in general practice in country districts where modern diagnostic methods are not easily accessible.

## 416. The Etiology of Bronchial Asthma.

F. M. RACKEMANN and D. S. KING (*Boston Med. and Surg. Journ.*, August 19th, 1926, p. 347), investigating the causes of bronchial asthma, have made numerous experiments with suspensions of house dust, and have obtained immediate positive local reactions after hypodermic injections of house dust suspensions in 36 per cent. of all asthmatics. Although in many instances different dusts were used in the treatment of the same patient, no single suspension gave better results than any other. The importance of dusts is also diminished by the fact that general urticarial and possibly asthmatic reactions, so easily produced with extracts of specific pollens, animal hair, or skin debris, did not occur after large doses of dust extracts in patients who showed a skin reaction to them. Another possible cause of asthma is hypersensitivity to bacteria; the authors have used stock cultures of three types of bacteria commonly found in the sputum of asthmatics—namely, *Staphylococcus aureus*, *Streptococcus haemolyticus*, and *S. viridans*. They conclude that asthma of extrinsic origin seems to be independent of any bacterial factor in its early stage. Attacks following contact with horses or cats are sharp and brief, unless complicated by a secondary respiratory infection. In many cases there was evidence that respiratory infection, rather than exposure to dust, was the cause of an attack. Treatment of 95 asthmatic patients with dust extracts produced good results in 15 cases only; some of these patients had other treatment simultaneously.

## 417. Pulmonary Arterio-sclerosis.

H. VAQUEZ (*Paris Méd.*, July 3rd, 1926, p. 15) reviews the various theories which have been advanced in explanation of the occurrence of this disease. In 1910 Giroux showed that pulmonary arterio-sclerosis was almost always secondary and consecutive to diseases of other organs, such as tuberculosis and emphysema, or to heart disease, especially mitral stenosis; in other cases it is apparently idiopathic. The disease is usually accompanied by extreme cyanosis, dyspnoea, blood-stained sputum, or even attacks of haemoptysis. In advanced cases of pulmonary arterio-sclerosis the aorta and its branches are often quite healthy. Skiagrams may show considerable enlargement of the right ventricle and auricle, with thickening of the branches of the pulmonary artery and of the roots of the lungs. Vaquez adds that pulmonary arterio-sclerosis occurs in two widely different forms—(1) as a terminal stage of certain diseases of the heart and lungs, and (2) as an unusual idiopathic disease producing a clinical syndrome, of which the etiology and mechanism have as yet received insufficient attention.

## 418. Well's Disease in Holland.

A. H. VAN GELDER (*Nederl. Tijdschr. v. Geneesk.*, July 31st, 1926, p. 524) refers to the previous cases of Well's disease reported in Holland by Goudsmit, Hammer, and Wolff in Zaandam, Schuffer and Ruys in Rotterdam, and Kronmenie (*Epitome*, October 10th, 1925, para. 288) and Enneking in Amsterdam (*Epitome*, July 19th, 1926, para. 612). He remarks that most of the cases of this somewhat uncommon disease reported in foreign literature have occurred in small epidemics connected with mines and swimming baths, whereas the Dutch cases were all isolated. He now reports an outbreak of eight cases in Delft. Only four presented the typical symptoms of Well's disease, though the serological tests were positive in all, and three had no jaundice. In six cases at least the disease could be traced to a pool in Delft swarming with rats infected with *Leptospira icterohaemorrhagiae*. Apart from the serological findings the most constant change was loss of hair, but as this did not occur till convalescence it did not possess much diagnostic value. All the patients recovered, so that the mortality of Well's disease in Holland has now been reduced from 75 to 25 per cent.

## 419. Blood Examination in Childhood.

E. STRANSKY (*Wien. klin. Woch.*, July 22nd, 1926, p. 865) gives instances of the value of a blood examination as a help to diagnosis in childhood. One child with only vague head symptoms showed a white blood count of 12,400 per c.mm. of which 89 per cent. were polymorphonuclears, thus suggesting meningitis, which was later confirmed clinically. He mentions its value similarly in poliomyelitis and pyaemia. Blood examination is also an aid to prognosis in such cases as acute infections. A child with multiple pyaemic abscesses had a count of red cells 4,000,000, haemoglobin 75 per cent., and white cells 20,000. The child then appeared to get worse in every way, but a second count showed red cells 4,320,000, haemoglobin 67 per cent., and white cells 56,000; a good prognosis was therefore given and proved to be correct. In infectious diseases such as pertussis the blood count is also of use; a leucocytosis with a high percentage of lymphocytes, in conjunction with a suspicious cough, is held to justify a diagnosis being made.

864 B

## Surgery.

## 420. Sarcoma of the Prostate.

R. R. SMITH and W. R. TORGERSON (*Surg., Gynecol. and Obstet.*, September, 1926, p. 328), who have collected 84 cases of sarcoma of the prostate, including one in a man aged 31, which came under their own observation, state that 30.5 per cent. of the reported cases occurred during the first ten years of life, and that it was more common during that decade than in any subsequent one. In about 60 per cent., however, it occurred in adult life (over 20 years). The onset is insidious at all ages, the first symptoms being almost always referred to the rectum or bladder. Pain, which sooner or later is almost always present, is severe and may radiate in almost any direction, but usually passes through to the sacrum or down the limbs. Haematuria is sometimes present, especially in the adult. Secondary anaemia, oedema of the extremities, and cachexia are late symptoms. Complications such as cystitis, pyelitis, or pyelo-nephritis are not uncommon. Peritonitis or bronchopneumonia may supervene as a terminal complication. In children the disease must be diagnosed from tuberculosis or abscess, and in the adult from hypertrophy of the prostate; carcinoma and echinococcus cyst must also be excluded. The round-cell type of sarcoma is the most frequent and the spindle-cell next. Metastases occur in about 40 per cent. of the cases and are very apt to be in the osseous system, especially the ribs and vertebrae; they are equally frequent in the lungs. The prognosis is wholly bad; all the patients in the authors' series succumbed. The round-cell type is the most malignant. Treatment is mainly palliative, and consists in relieving urinary obstruction and keeping the patient comfortable.

## 421. Pruritus as a Prodrome of Mammary Cancer.

J. H. VERHAVE (*Nederl. Tijdschr. v. Geneesk.*, September 4th, 1926, p. 1082), who records an illustrative case, states that pruritus as a prodromal symptom of malignant growths, though uncommon, is a prominent symptom, being better known as an initial manifestation of lymphogranuloma and leukaemia. Several authorities, such as Fordyce, Wickham, Jadassohn, Sack, Besnier, and Doyon, have noted its occurrence in cancer of the liver and stomach when the patient's nutrition was good, so that cachexia, icterus, and diabetes could be excluded. The symptom also occurs in cancer of the buccal mucous membrane and tongue. The pruritus may be local or general. According to Jadassohn the pruritus is due to the autotoxic action of the tumour itself or to the change in the chemistry of the alimentary canal caused by the growth, while Friedrich Müller regards the toxins produced by the tumours as responsible. In 5 out of 125 cases of mammary cancer in Noordenbos's clinic Sanders, in his Amsterdam thesis (1925), states that pruritus occurred, whereas pain in all these cases was insignificant. Verhave's patient, who was a woman aged 37, had complained of itching in her right breast for months, but had never had any pain in the breast or arm and had not lost flesh. On examination a tumour, measuring 5 cm., was felt in the left lower quadrant of the breast. The diagnosis of cancer of the breast was confirmed at the operation, when small metastases were found in the axilla.

## 422. Accessory Pancreas in the Stomach Wall.

K. GRIEP (*Zentralbl. f. Chir.*, August 21st, 1926, p. 2147), who has previously reported a case of an accessory pancreas in the anterior wall of the stomach in the region of the fundus, now records two examples of an accessory pancreas situated in the pyloric area in a man aged 68 and a woman aged 49 respectively. In spite of its origin in embryonic life, the symptoms due to the presence of an accessory pancreas did not develop until middle-age. Although several cases of an accessory pancreas in the stomach wall have been published in recent years it is still hardly possible to make a correct diagnosis during life, even in the course of an operation, as the symptoms suggest gastric ulcer, carcinoma, or gall stone. In Griep's cases a diagnosis of cancer of the stomach was made, and the Billroth I operation was successfully performed. Griep regards resection in cases of accessory pancreas as the method of choice when the condition cannot be distinguished from carcinoma.

## 423. Complete Transposition of the Viscera.

Situs inversus viscerum, as M. CLEVELAND (*Archives of Surgery*, September, 1926, p. 343) recalls, is that condition in which the normal arrangement of the viscera is reversed so that a kind of mirror picture of the usual position is obtained. Such transposition is usually total, but may in rare instances involve either the thoracic or the abdominal viscera alone. The frequency of the condition is doubtful; at the Mayo

Clinic out of 347,000 cases ten of visceral transposition were recorded. Most patients so affected seem to differ in no way from the normal human being; they are not left-handed and heredity plays no part. Various theories have been advanced to explain the condition—such as a right spiral winding of the umbilical cord, the turning of the embryo to the right side of the umbilical vessels instead of the left as normally occurs, and the effect of anomalies of the abdominal veins. All, however, fail to explain the basic cause of the condition. A case is recorded in full detail which had been recognized during lifetime and was fully examined after death. There was complete transposition of the viscera with a fused kidney. The report is illustrated with numerous photographs to show the relations of the different organs.

#### 424. Adenomyoma of the Pylorus.

E. POZZI and R. PALAZZO (*Rev. Sud-Amér. de Endocrin.*, August 15th, 1926, p. 682), who report the first case of the kind to be published in the Argentine, state that the clinical history of adenomyoma of the pylorus is generally that of gastric disturbance, the duration of which varies from a few to twenty years. The symptoms consist of dyspepsia, flatulence, pyrosis, local pain, and loss of weight. Their patient was a man, aged 23, who had suffered from gastric symptoms in the form of dyspepsia, flatulence, and dull epigastric pain for the previous nine months. Some months later vomiting of food developed, but was never accompanied by haematemesis. In the course of nine months the patient lost 11 lb. Examination of the gastric juice showed 0.54 gram of free hydrochloric acid with a total acidity of 1.34 grams per cent. The blood count showed 4,020,000 red cells and 6,000 leucocytes, a haemoglobin value of 100 and a normal differential count. The Wassermann reaction was positive; x-ray examination revealed gastric dilatation and ptosis with slow evacuation of the contents. The stomach showed a large air chamber and a slightly bilobular appearance. As no improvement followed injections of mercury and sulfarsenol the patient was sent to a surgical ward with the diagnosis of pyloric ulcer. At the operation a nodule the size of a large hazel-nut was found on the posterior surface of the pylorus; resection of the pylorus and Polya's anastomosis were performed. Histological examination of the tumour showed that it consisted of smooth muscle and glandular tissue, some of which resembled Brunner's glands, and some pancreatic tissue.

#### 425. The Value of Jejunostomy.

T. G. ORR and R. L. HADEN (*Journ. Amer. Med. Assoc.*, August 22th, 1926, p. 632), as the result of experimental work upon dogs, are doubtful whether the operation of jejunostomy in cases of acute intestinal obstruction and paralytic ileus is so valuable as has been considered. They found that the chemical changes of the blood characteristic of acute obstruction of the jejunum were not prevented by jejunostomy, and that this operation tended to shorten, rather than lengthen, life. Animals with a simple jejunostomy were found to die more quickly than those in which obstruction of the jejunum was present. The administration of sodium chloride solution tended to prolong life whether jejunostomy was performed or not. In view of the danger of duodenal fistula and the rapid death of animals following experimental jejunostomy, the authors believe that the clinical value of jejunal drainage for obstruction of the small intestine has yet to be established.

#### 426. Tonsillectomy as a Preventive of Subacute Bacterial Endocarditis.

Owing to the apparent rarity of a history of tonsillectomy together with the presence of tonsillar tissue in patients with subacute bacterial endocarditis K. B. TURNER (*American Heart Journ.*, August, 1926, p. 747) thought that removal of the tonsils might prevent this disease. He classified the records of 300 hospital cases into three groups, the first being 100 non-rheumatic ordinary patients; the second, 100 cases admitted with a diagnosis of acute rheumatic fever; and the third, 100 cases of subacute bacterial endocarditis. In the first group there was a history of complete tonsillectomy in 16 per cent., and of partial in 3 per cent.; in the second the figures were, total 31 per cent., partial 7 per cent.; and in the third the figures were, total 4 per cent. and partial nil. The low incidence of earlier tonsillectomies in the subacute bacterial endocarditis group is striking, and is more noticeable when compared with the relatively high incidence in the group of rheumatic fever cases, a group which may be considered as a potential "feeder" for the subacute bacterial endocarditis group. Turner concludes that there seems a possibility that tonsillectomy in cases of rheumatic fever or rheumatic heart disease may tend to prevent subsequent subacute bacterial endocarditis.

## Therapeutics.

#### 427. Yatren in Amoebic Dysentery.

J. FUNKE (*Therapeutic Gaz.*, September 15th, 1926, p. 621) describes the use of yatren, which is an iodo-oxyquinoline sulphonic acid compound, in amoebic dysentery; he believes that it will replace ipecacuanha to a large extent, and is also superior to stovarsol. His procedure is as follows: About two hours after the evacuation of a cleansing enema of 2 litres of warm water containing 2 drachms each of sodium bicarbonate and sodium chloride, the dose of yatren dissolved in 200 c.cm. of warm water is introduced by the rectum, as high as possible, and retained all night. On the first and second nights the dose is 5 grams; it is increased to 6 grams on the third and fourth nights, to 7 on the fifth, to 8 on the sixth and seventh, to 9 on the ninth, and to 10 on the five following nights. An interval of seven days follows, and then seven daily doses are given of the last concentration used. In some cases colonic irritation follows, even to the extent of blood appearing in the stools; in such patients the increase of the dose is necessarily more gradual. The amoebae rapidly disappear from the stools, but in chronic cases of dysentery, where the parasites are buried in the submucosa or the liver, the treatment must be repeated at intervals for some months. Yatren can also be given intravenously, and Funke states that, apart from the irritation of the intestinal wall already mentioned, he has seen no untoward effects from intravenous doses as high as 500 mg.

#### 428. Sublingual Administration of Strophanthin.

J. L. TRACY (*Med. Journ. and Record*, September 15th, 1926, p. 340) reports a case of post-influenzal cardiac failure with general oedema in which great benefit was derived from the use of strophanthin administered in small doses sublingually. A solution in water of strophanthin was prepared, containing one-hundredth of a grain to the minim, and at intervals of two hours 1 minim was placed beneath the tongue; after six such doses the interval was increased to four hours. Before the administration the patient was orthopnoeic, with a severe cough and respirations about 60 a minute; the superficial tissues of the body and limbs were almost boardlike, and no radial pulse could be felt or heart sounds heard. Within five minutes of the first administration there was pronounced diminution of the cardiac distress, and twenty-four hours later the swelling had so subsided that the radial pulse could be detected; to this latter effect the use of magnesium sulphate and strychnine had contributed. With the cessation of the influenzal condition examination of the heart became possible, and long-standing mitral and aortic disease was detected. The administration of strophanthin was continued in a dose of a sixtieth of a grain, three or four times a day for four months, and steady improvement followed. Tracy considers that, owing to the serious cardiac condition, it will be necessary to continue its use for the remainder of the patient's life, but he adds that it can easily be given in the form of uncoated tablets, dissolved in a drop of water and placed in the mouth. He suggests that its administration in this way brings it into direct contact with nerve endings and enables it to have an effect on the sympathetic system of the heart.

#### 429. The Value of Mercurochrome-220 Soluble in Therapeutics.

H. H. DAVIS (*Amer. Journ. Med. Sci.*, September, 1926, p. 340), after reviewing the literature and carrying on some experimental work on the value of mercurochrome-220 in various conditions, concludes that, while intravenous injections of this agent are useful in the treatment of septicæmia and other infections, yet its employment should not be considered to have passed out of the experimental stage. Its use is not without risk, and it should, therefore, not be given indiscriminately, but be reserved for desperate cases. Intracavitary injection is dangerous because of the local irritant reaction, which is often followed by very severe general reaction. The author cites the findings of J. E. Walker, who showed experimentally that staphylococci and streptococci grew better in blood containing mercurochrome in a dilution of 1 to 25,000, than in normal blood. With increased concentration bacterial growth became more profuse, reaching a maximum at 1 in 400 for the staphylococcus and 1 in 800 for the streptococcus. When used in wounds, sinuses, or serous cavities Davis considers that the dose of mercurochrome should be limited to 5 mg. per kilogram of body weight, since it is easily absorbed and may lead to severe reaction or stomatitis. Its solution in a mixture of alcohol, acetone, and water is recommended as a satisfactory antiseptic before operation.

**433. Digitalis in the Treatment of Auricular Premature Contractions.**

IN the opinion of H. J. STEWART (*American Heart Journ.*, August, 1926, p. 637) the indication for the treatment of heart irregularities depends on two considerations: first, whether there are signs of heart failure as the result of the presence of the irregularity; and, secondly, whether there are subjective symptoms of discomfort from the irregularity itself. The therapeutic use of digitalis has been extensively studied in auricular fibrillation and in auricular flutter, but accurate information concerning its effect on the irregularities due to the various types of premature contractions is wanting. The effect of digitalis (digitan—Merck) on auricular premature contractions has been studied by the author in a lad aged 18, and he found that full therapeutic doses of the drug never failed to bring about complete disappearance of the premature beats. Recurrence could be prevented by maintenance doses of the digitalis, but the symptoms reappeared if the drug was discontinued and the digitalis effect allowed to wear off. From his observations Stewart concludes that digitalis is effective in cases of auricular contractions which occur spontaneously, but that the drug must be used in the full therapeutic amount. Repeated electrocardiogram tracings were taken. While the patient was under the influence of the digitalis the injection of atropine was not followed by a return of the premature contractions. When digitalis was not being given and the premature contractions were present they were stopped for twenty-four hours by an injection of atropine.

**434. Scarlet Fever Antitoxin.**

H. B. CUSHING (*Canadian Med. Assoc. Journ.*, August, 1926, p. 937) records his observations at the Alexandra Hospital, Montreal, on 500 cases of scarlet fever treated with serum, some prepared by the Dick method, some by the Dochez method, and some by a combination of both methods. The usual dose was 10 c.cm. given intramuscularly as early in the disease as possible. The dose was only occasionally repeated, and in a few toxic and septic cases was given intravenously. The serum was given to all cases, except the extremely mild ones with a temperature below 100° F. At the Alexandra Hospital the mortality for scarlet fever always used to be over 5 per cent., but has been falling in recent years. In 1923 it was 3.25 per cent., and in 1924, when convalescent serum was used in serious cases, 2 per cent. Since the general use of antitoxin there have been 800 cases and 10 deaths, or 1.2 per cent. None of the deaths, however, was due to scarlet fever alone, among the cases treated with serum, but the cause of death was some intercurrent disease; 13 per cent. had a serum rash. Cushing concludes that scarlet fever antitoxin is a specific remedy which cuts short the fever and relieves all its early manifestations; it lessens the number and severity of the complications, and definitely lowers the mortality of the disease. The serum, therefore, should be given to every case of scarlet fever at the earliest possible moment, the amount being regulated according to the severity of the attack, and the dose promptly repeated if the first proves inadequate.

**435. Serum Therapy in Acute Myelitis.**

G. ETIENNE (*Presse Méd.*, September 18th, 1926, p. 1185) reports 26 cases of acute myelitis, 17 of which were treated by injection of an antipoliomyelitic serum prepared by the Pasteur Institute. Of these patients 9 were completely cured and restored to their previous healthy condition, one was almost cured with very slight persistent sequels, and one died. Of 3 patients treated with insufficient doses progress of the disease was arrested in 2 and death occurred in one after a second outbreak. Three cases already in extremis died very soon after injection. Etienne considers that the effective dose of serum is 100 c.cm. daily. In one case where a milk injection caused some slight improvement, serum injection brought about a rapid and complete cure, which suggests that the serum has a specific effect and does not act merely as a serum.

**436. Rectal Administration of Adrenaline.**

W. C. MENNINGER and H. S. HEIM (*Amer. Journ. Med. Sci.*, September, 1926, p. 425), as the result of experimental study of the rectal administration of adrenaline in man, conclude that it might prove to be of value in asthma or Addison's disease, where a prolonged effect and repeated doses are required. They found that the maximum effect was reached in about forty minutes after administration, and that the duration of the rise in blood pressure was forty-five minutes or more. When relatively large doses were tried they found that the rectal absorption of adrenaline was unreliable, little or no effect being produced in about 50 per cent. of the cases. Of thirty-one patients examined, seventeen showed a blood pressure rise of over 10 mm. of mercury, and in fifteen it reached 20 mm.

**Laryngology and Otology.****437. Displacement Irrigation of the Posterior Nasal Sinuses.**

A. W. PROETZ (*Arch. of Oto-Laryngol.*, July, 1926, p. 1) describes his lavage treatment of the posterior sinuses of the nose, and explains how it is adapted for examination by radiography. He evolved this method on account of the great difficulty in reaching and investigating the sphenoidal sinus and posterior ethmoidal cells without operative measures. The patient is placed in the supine position and the head is extended at the atlanto-occipital joint until the chin and the external auditory meatus are in the same vertical plane. By this means the sphenoidal sinus becomes the most dependent part of the nasal cavity. Normal saline solution is now allowed to flow into the nose until the ostia of the sinuses are submerged; it does not yet enter the sinuses, as the air cannot escape through the narrow ostium. A suction nozzle is applied to one nostril, the other one is closed and the tongue and palate are kept in the "K" position to close the nasopharynx. Gentle suction of not more than 3 lb. is employed and intermittently released. Each suction draws a bubble of air from the sinuses, and each release allows a drop of fluid to enter the cavity. About a dozen alternations are usually sufficient to fill the posterior group of sinuses. The patient is then returned to the erect position. The fluid remains in the sinuses for from eight hours to several days. Proetz obtained very satisfactory therapeutic results with saline solution, and has never tried more complicated solutions. The treatment is repeated at intervals of from three to eight days. The sinuses are rapidly cleared of mucus and muco-purulent discharge, and the inflammation subsides. He states that the method is not applicable where there is advanced disease with polypoid degeneration of the mucosa or bone necrosis. The method was found particularly useful for diagnosis in conjunction with radiography, and in this case the fluid used was an iodized oil or some similar radio-opaque fluid. The author does not think that there is any danger of infection of the Eustachian tubes, since sufficient fluid can be instilled into the nose without reaching the level of the Eustachian orifices, and the suction employed is not enough to draw any air out of the middle ear.

**438. Cancer of the Larynx.**

ST-CLAIR THOMSON (*Arch. Internat. de Laryngol.*, May, 1926, p. 513) states that in treating a cancerous laryngeal growth there must be no preconceived idea that the whole organ must be removed. In intrinsic carcinoma of the larynx the invariable sign of roughening of the nose should lead the patient at an early date to the laryngologist while the tumour is still limited. An early diagnosis enables laryngofissure to be performed; this operation should be almost devoid of risk to the life of the patient, leaves a useful voice, and is followed by a definite cure. If the case is seen too late, or there is recurrence, good results can be obtained by a partial laryngectomy. Extrinsic carcinoma is rarely operable, and then only by lateral pharyngotomy. Complete laryngectomy is rarely of any value in the extrinsic growth, but is of value in the late cases of intrinsic growth. The occurrence of late growth is becoming rarer owing to the education of the public, and in consequence the operation of complete laryngectomy is becoming increasingly rare, while laryngofissure is the operation which will be performed in the majority of cases and with the best results in the future.

**439. Cerebro-spinal Rhinorrhoea.**

J. BARRETT (*Med. Journ. of Australia*, August 7th, 1926, p. 182) reports a case of cerebro-spinal rhinorrhoea in a man, aged 38, who had suffered from slowly increasing deafness until a year previously, since when there had been no increase, but he had constant pain in the head. He had had a septal resection of the nose two years before. The nose, throat, and accessory sinuses were fairly normal. The optic discs, especially on the left side, were slightly blurred and the vessels were waxy; the elevation of the left disc was about two diopters and of the right about one diopter, the latter being five diopters three weeks later. On stooping cerebro-spinal fluid ran from the right nostril. He became rapidly worse, with symptoms of a gross intracranial lesion, and intense pressure was present when a temporal decompression was performed. At the necropsy large Cushing's bilateral tumours of the acoustic nerve were found. The patient had cerebro-spinal rhinorrhoea, which is usually associated with optic neuritis and raised intracranial pressure, the fluid apparently escaping through the ethmoid plate. The type of deafness resembled ordinary middle-ear deafness and was unlike that usually associated with cochlear or nervous disease; although he was not totally deaf and both auditory nerves were profoundly involved neither vertigo nor nystagmus could be

produced by any caloric test. The involvement of the auditory nerve proved to be largely extracranial, although the condition led to the provisional diagnosis of an intracranial lesion after the division of the auditory and vestibular fibres in the brain. The removal of the tumours by operation would have been practically impossible.

## Obstetrics and Gynaecology.

### 437. Treatment of Dysmenorrhoea.

B. SCHWÖBER and R. WICHMANN (*Zentralbl. f. Gynäk.*, August 7th, 1926, p. 2075) have treated 158 cases of primary dysmenorrhoea, in which no genital abnormality other than a small uterus could be found, by the following method of operative dilatation. The cervix and the uterine cavity were dilated by introduction of each of Hegar's dilators up to No. 10 for one minute, and then the region of the internal os was incised by Lymer's metrotome. Hegar's dilators were then introduced up to No. 16, which was left in place for two minutes. Finally, a drain of sterilized gauze impregnated with oil was passed through the cervix to the fundus. The gauze was withdrawn from seven to ten days later. Of the 91 patients from whom details of the subsequent history could be obtained, about 15 per cent. were no better, 22 per cent. had found some relief, 13 per cent. had been free from menstrual pain for at least twelve months, and 50 per cent. appeared to be cured permanently. The results were distinctly better in those women whose menstrual period lasted from three to six days than in those who menstruated longer.

### 438. Diagnosis of Foetal Cardiac Abnormalities.

J. J. SIMPSON, R. L. McALLAN, and W. J. KERN (*American Heart Journ.*, August, 1926, p. 717) report a series of phonocardiographical studies to determine the duration and pitch of the foetal heart sounds and the duration of systole and diastole; they tried also to establish criteria for the pre-natal recognition of congenital heart lesions or abnormalities. An electrical amplifying and filtering stethoscope and a string galvanometer were used to record the heart sounds. Foetal phonocardiograms were obtained in 33 cases, and in these the character of the first sound was symmetrical, with a crescendo and a decrescendo phase on either side of a peak, the second sound being slightly eccentric in form and showing a longer period of vibration following the peak than preceding it. Lewis's chief criterion of a recorded murmur was a high frequency, but the authors found an alteration in the symmetry of the sound picture to be a more valuable method of identification. The average duration of the first sound in all pre-natal cases was 0.058 second, with a minimum of 0.03 and a maximum of 0.03 second; in the case of the second sound it was 0.042 second, with a maximal 0.06 and a minimal 0.03 second. In post-natal cases the first sound averaged 0.064 second, with a maximum of 0.08 and a minimum of 0.04 second; and the second sound 0.043 second, with a maximal 0.07 and a minimal 0.02 second. The authors also found a variability of normal heart sounds before and after birth, and state that an early systolic murmur is almost universal in early infancy. Of the 33 cases, 12 presented no murmurs, 17 showed an early systolic murmur only, while 4 showed other systolic and diastolic murmurs which were possibly caused by currents through the patent foramen ovale and ductus arteriosus. In one case before birth a high-pitched murmur was present throughout the whole of systole, which was indicative of a congenital heart lesion—namely, pulmonic stenosis. In the normal foetus with a patent foramen ovale and ductus arteriosus murmurs were not consistently found; presumably it requires either abnormal pressure relations, developmental defects occurring early in intrauterine life, or both, to produce the auditory signs of a congenital lesion.

### 439. Peruterine Insufflation for Sterility.

I. C. REYN (*Amer. Journ. Surg.*, July, 1926, p. 1) discusses the diagnostic value and therapeutic application of peruterine insufflation of the Fallopian tubes with carbon dioxide in cases of sterility. The apparatus and technique are described, the most important factor for scientific and safe application being the maintenance of a uniform pressure, rate of flow, and volumetric control. With a uniform rate of flow of fifteen seconds to 100 millimetres of mercury two pulsations of the volumeter generally sufficed to establish a subphrenic pneumoperitoneum with its associated clinical sensations of epigastric distension and pain in the shoulders and diaphragmatic region. Each pulsation represented from 30 to 40 c.cm. of gas, and though it was found that obese patients might require from three to five pulsations the quantity rarely exceeded 200 c.cm. The patient was examined radiologically on rising from the table; if the

tubes were patent the presence of a single or double-sided subphrenic pneumoperitoneum was demonstrable. The author states that with one tube closed the patient will complain of pain on the side of the obstruction, and if both tubes are closed the pain will be bilateral. Such pain is complained of when the obstruction is at any point beyond the isthmus, but when the closure is at the intramural portion of the tubes or very near the isthmus the pain is in the mid-line and referable to the suprasymphyseal area. Rubin found these symptoms so pathognomonic of the site of obstruction as to obviate the necessity for the injection of opaque solutions except where operative intervention was indicated. It is claimed that the method has a definite prognostic and diagnostic value in primary sterility when other contributory causes have been eliminated, in cases where there has been previous pelvic infection but which are at the time free from symptoms, and in other conditions in which the tubes have been operated upon. Especially is it of service as a therapeutic measure to eliminate the tubal factor in sterility, and in obscure cases it avoids the necessity for surgical exploration, since it usually affords a means of determining the patency of the tubes.

### 440. Abnormal Passage of the Foetus in Spontaneous Labour.

M. COPPOLA (*Rev. d'Obst. e Ginecol. Prat.*, September, 1926, p. 374) reports the case of a primipara, aged 23, who delivered herself at term spontaneously, without medical supervision, of a living child presenting by the vertex. There was no excessive haemorrhage or shock, but a large extraperitoneal rupture of the lower uterine segment, involving muscle and mucous membrane, was found to have produced an extensive communication between the uterus and vagina. The external os was intact and virginal. There was no disproportion in size between the pelvis and foetus. In a second case a primipara, aged 25, gave birth spontaneously at term to a living child; the head had passed through a large central perineal rupture, but this did not reach as far as either the rectum or fourchette. The posterior vaginal wall was extensively torn, but there was no undue amount of haemorrhage. In this case also the pelvis was of normal size, and Coppola ascribes the abnormal transit of the head in both cases to congenital abnormalities of the lower uterine musculature and the perineum respectively.

### 441. Tuberculosis in Late Pregnancy.

A. COUVELAIRE (*Gynecol. et Obstet.*, 1926, xiii, 6, p. 428) states that since 1922 there has been close association between the Maternité Baudelocque and tuberculosis dispensaries in Paris, a separate pavilion in the former having been set apart for tuberculous women in labour. When separation from the mother is considered necessary, the infants are placed in approved families or institutions till the age of 4. In five years 315 confinements of women with active pulmonary tuberculosis were conducted in the Maternité; treatment of the tuberculosis was maintained up to labour, artificial pneumothorax being induced in 57 of the patients. The pregnancy was invariably allowed to take its natural course; Couvelaire doubts whether hysterectomy or induction of labour has any useful function in treatment. Four Caesarean sections were performed on patients in *extremis*, and two after death; no foetus survived in any of these cases. About 40 per cent. of the first hundred patients who were treated died before or during labour or within a year afterwards. Of those with almost quiescent fibrous disease, the great majority seemed little affected by pregnancy, but in those with active disease acceleration was usually noted during or after pregnancy, so that nearly half were dead within twelve months of labour. Of the 315 labours, 288 led to live birth of apparently viable infants, of whom 17 per cent. weighed more than 7½ lb. and 51 per cent. less than 6½ lb., as compared with 24 and 41 per cent. respectively in a series of non-tuberculous cases. Of 280 infants, 44 died within the first month and 8 between the first and the fourth months, in spite of absolute separation from the mother from the time of birth. With more thorough medical and nursing supervision and treatment the mortality of the first month has been reduced recently from 33 to 12 per cent. Generally the cause of death could be traced to bronchopneumonia, intestinal infections, or digestive troubles, but a certain number of infants showed during life few digestive or pulmonary symptoms, a negative cutaneous reaction for tuberculosis, and no pyrexia, while after death no morbid conditions of the viscera were detected. The syndrome of progressive denutrition in these cases of unexplained disease is compared by the author to the extinction of a lamp which is short of oil. Similar findings have been reported at the Laënnec clinic and in experimentally inoculated animals; they are met with also in the infants of syphilitic parents, including those who have responded well to treatment. Only one of the

infant deaths was due to tuberculosis (tuberculous bronchopneumonia), and in this case the separation of the mother and child had not been complete. The majority of the first series of 65 infants are still living.

## Pathology.

### 442. The Titration of Tetanus Toxin and Antitoxin by Flocculation.

G. ABT and MLE B. ERBER (*Ann. de l'Inst. Pasteur*, August, 1926, p. 659) have examined the applicability of the flocculation method to the titration of tetanus toxin and antitoxin. The quantity of toxin found most satisfactory was 4 c.cm.; to this is added the serum, which is used either undiluted or diluted one-half or two-thirds; the tubes are incubated in a water-bath at 45°C., and examined frequently for the first sign of flocculation. Ten batches of toxin were employed, all of about the same potency, killing a mouse in a dose of 1/20,000 c.cm. The standard serum had been kept in powdered form for two years and contained 200 American units. Flocculation occurred in two or three hours in a mixture of 4 c.cm. of toxin and 0.16 c.cm. of standard antitoxin. Since this quantity of serum contains 32 units of antitoxin, it follows that 1 c.cm. of toxin was able to neutralize 8 c.cm. of antitoxin. Having titrated the toxin, they used this for standardizing their test serums. Mixtures were put up each containing 4 c.cm. of toxin and varying quantities of serum; that mixture was considered to be neutral which first showed flocculation. The rapidity with which flocculation occurred varied with the particular batch of serum; in a group of 51 serums 18 flocculated in two to four hours, 23 in seven to eight hours, and 6 after twenty hours; 4 serums showed no flocculation at all. Generally speaking, the stronger the serum the more rapid was the flocculation; but this rule was not invariable. A certain number of comparisons were made between the titre of the serum obtained by flocculation and that obtained by animal inoculation. Of 38 serums 24 gave perfectly concordant results by the two methods; in the remainder there was a discrepancy—in one instance of 30 per cent. The number of animals available for titration was, however, too small; to this is attributed the discrepancies observed. They found that the weight of the precipitate in neutral mixtures of toxin and antitoxin was almost identical, independently of the strength of the toxin or antitoxin. They conclude that the flocculation method is suitable for the titration of the majority of antitetanic serums, since the results can be read in twenty hours; this is a great saving of time. The few serums that do not flocculate can be titrated by the animal method.

### 443. Regulation of Capillary Flow.

T. LEWIS (*Heart*, August 9th, 1926, p. 1) records observations upon the regulation of blood flow through the capillaries of the human skin. From the investigation of his own skin and of others under natural conditions he concludes that the majority of the capillaries are open, that their tone is relatively stable and unfluctuating, and that the belief that they are constantly opening and closing is incorrect. It is shown that skin mottling is a normal phenomenon in children and adults; the areas involved are relatively constant in form and position, representing anatomical skin areas which depend upon some vascular or nerve structure in the skin. Such areas are more or less constant in their contour and location when the subject is at rest, and there is a tendency when any change has occurred for the previous pattern to be resumed. No material alteration results from external changes in temperature nor from venous congestion; the mottling returns after arrest and release of the circulation, the capillaries remaining open and not continually opening and closing. Lewis considers that the tone in the arterioles is a coarse adjustment under nervous control, while that in the endothelial vessels is a finer adjustment controlled locally by the tissue needs; he adds that skin mottling (*cutis marmorata*) is due to local differences in the tone of the minute vessels.

### 444. Pathology of Pancreatic Inflammation.

B. F. DAVIS (*Minnesota Med.*, September, 1926, p. 507) reports three cases of pancreatitis and discusses the pathology of this condition. Secondary inflammation of the pancreas occurs in the course of infectious diseases, particularly small-pox and typhoid fever; the gland cells show cloudy swelling, and the hyperaemic interstitial tissue is infiltrated by a cellular exudate. The cloudy swelling may pass into fatty degeneration, or, more rarely, definite cavities are formed containing cellular debris, and leading to peritonitis. This type is occasionally associated with haemorrhage into the pancreatic

substance. In the gland and its neighbourhood become a mass, with numerous areas of fat necrosis which much resembles that produced by activated trypsin in experimental animals, and is believed to result from the passage of bile or intestinal juice into the pancreas. In suppurative pancreatitis due to such causes as pyaemia, or to extension of inflammation from a perforated gastric or duodenal ulcer, the gland alveoli become distended with pus, and necrosis follows the isolation of areas by interference with their blood supply. In chronic fibrous pancreatitis the gland tissue disappears and there is an overgrowth of the inter- and intra-acinous connective tissue. Such a condition is occasionally found in diabetic patients, or may follow congenital syphilis, the impaction of gall stones, and carcinoma of the head of the pancreas or of the duodenum. Infection may reach the pancreas by the lymph stream from the gall bladder, or by the blood vessels. The author gives details of two cases in which infection appeared to have reached the pancreas from the mouth and antrum.

### 445. Mycotic Aneurysms Involving the Intraventricular Septum.

C. P. WILSON (*American Heart Journ.*, August, 1926, p. 703) reports three cases of a rather unusual complication of a fairly common clinical picture—namely, mycotic aneurysms of the intraventricular septum complicating subacute bacterial endocarditis. The first patient had the typical symptoms of fulminating endocarditis, except that no positive blood culture was obtained during life, and the necropsy findings were those of a mycotic aneurysm involving the intraventricular septum, but not the bundle of His. The lesion was probably engrafted on healthy valves. In the second case a very typical picture of Adams-Stokes' disease was caused by the mycotic aneurysm. The patient died suddenly of heart-block, one positive blood culture (short-chained Gram-positive diplococci) having been obtained during life; the acute endocarditis affected previously damaged valves. The third patient died very suddenly, apparently of acute heart-block associated with pulmonary oedema, the lesions probably being on healthy or only recently damaged valves. In the last two cases the bundle of His was involved in the destructive process with the development of heart-block. No positive blood culture was obtained during life in two of the cases, although post-mortem cultures of both hearts' blood and of the growths on the valves produced *Streptococcus viridans*. In the third case, in which one positive blood culture was obtained during life, the finding was confirmed after death by smears from the vegetations but not by culture.

### 446. Intracutaneous Tests with Streptococcus Strains.

G. JACOBSON (*Acta Paediatrica*, August 10th, 1926, p. 67) performed intracutaneous tests with filtrates in the dilution 1 in 100 from 34 streptococcus strains isolated from cases of various infectious diseases. The filtrates were tested on groups averaging 30 individuals each, of whom the majority were Dick-positive. The tests in 27 of the 34 strains gave consistently negative reactions, 6 gave a few positive reactions, but did not, however, follow the lines of the Dick reaction; only one filtrate entirely followed the Dick reaction. No pronounced difference was evident between the haemolytic and non-haemolytic strains in regard to the frequency of the positive reactions. Haemolytic streptococci were isolated in 23 of 50 apparently healthy throats in children. Haemolytic streptococci appeared to be present as often in Dick-positive as in Dick-negative children. With filtrates in the dilution 1 in 100 from streptococcus strains intracutaneous tests gave only negative reactions.

### 447. Blood Changes after Mercurochrome Injections.

S. O. BLACK (*Therapeutic Gazette*, September 15th, 1926, p. 613) records the results of observations upon the blood changes after intravenous mercurochrome injections. Notes of nine cases are given in which mercurochrome-220 was administered for various septic conditions, including cystitis, erysipelas, arthritis, perinephritic abscess, and cellulitis. It was found that within four hours of administration a marked increase in the leucocyte count occurred, reaching its maximum about the twelfth hour and then slowly falling to normal. Coincidentally with this there was a definite increase in the number of erythrocytes and a rise in the haemoglobin content reaching their maximum about the same time that the leucocyte count was highest. Examination of the urine four, eight, and twelve hours after the injection showed the presence of a heavy cloud of albumin and many casts where previously there had been none; this indicates that the dye acts as an irritant to the kidney. The injections were followed by a very marked reaction, which Black considers necessary if good results are to follow.

### 

#### 

F. HAMBURGER (*Monatsschr. f. Kinderheilk.*, August, 1926, p. 244) contests Burghard's statement that descending croup is always fatal, and that no information can be obtained from auscultation as to whether the diphtherial process has invaded the small bronchi or not. This invasion, which very often is limited to one part of the lungs, can frequently be detected by auscultation of the chest, definite impairment of the breath sounds being heard over the whole of the left or right side or over a single lobe. Hamburger also disagrees with Burghard's view that if no improvement has occurred twenty-four hours after injection of serum, the serum treatment has been started too late. It often happens that, after an aggravation of the condition in the first twenty-four hours, the process is arrested in the following twenty-four hours, and this arrest must be regarded as an effect of the serum. Loosening of the membrane does not always begin in sixteen to twenty-four hours, but often not until after thirty-six hours. Each case, he adds, is a problem in itself, and there is no definite sign that can be regarded as an indication for intubation.

#### 

C. W. HEMLITZ and S. NORLÉN (*Acta Paediatrica*, August 10th, 1926, p. 67) report that during an epidemic of catarrhal jaundice one of the cases ended fatally after an illness of eight days. During the last few days marked clinical symptoms developed corresponding to the picture of acute yellow atrophy. A prominent feature of the case was the capacity of the liver to excrete colouring matter. The pathological changes consisted in severe damage to the liver with considerable degenerative atrophy and unusual macroscopic and microscopic appearances. A particularly remarkable feature was that the greater part of the central portion of the lobules was preserved. The microscopic appearances agreed with the results of clinical examination of the hepatic function. On the other hand, the destroyed peripheral parts of the acini showed abundant regenerative changes and well marked round-celled infiltration. These changes are especially striking in view of the short clinical course. In contrast with these relatively mild changes in the liver were the other findings—namely, pronounced haemorrhagic diathesis with severe anaemia and jaundice, and changes in the other organs, especially the kidneys, which indicated a peculiar disturbance of calcium metabolism.

#### 

W. GOLDSTEIN (*Med. Klin.*, October 1st, 1926, p. 1527) states that the syndrome described by Still has been found in adults, not only by himself but by others. He describes fully a case of a woman, aged 38, who had enlarged glands and swollen joints. The hilus glands were enlarged, as was shown by x-rays, and the von Pirquet test was positive. The spleen was palpable, and a blood examination showed  $3\frac{1}{2}$  million red corpuscles and 1,600 white with a large preponderance of lymphocytes. The patient was treated by heliotherapy and arsenic. The joint and gland condition remained unaltered, but the blood picture became more satisfactory. Goldstein asserts that the chief characteristic of Still's disease is the site of the joint lesion—namely, in the per-articular tissues and not in the bone. A bacterial origin must be borne in mind and the possible connexion with the tubercle bacillus. But it is to be noted that the so-called tuberculous rheumatism is a separate entity in which there is shrinking of the capsule and actual destruction of the bone. Two cases are quoted where the *Streptococcus viridans* was obtained from the blood stream.

#### 

In a review of the literature on this subject, G. ICHOK (*Presse Méd.*, October 6th, 1926, p. 1255) states that a rational treatment of sea-sickness is based on a clear knowledge of the physiological mechanism of the symptoms. Pitching, much more than the rolling, of the vessel causes the malady, and prevention will only arrive when it is possible to make ships more stable. The difference in boats implies more than one kind of sea-sickness, and it would be quite true to speak of sea-sicknesses. Nolt has stated that sea-sickness is a vertigo of labyrinthine origin due to the abnormal excitation of the vestibular nerve by the unusual changes in the position of the body (see *Epitome*, 1926, vol. I, paras. 254 and 443). These reactions are easily explained by the fact that the vestibular

nerve is in immediate juxtaposition with the nuclei of origin of the salivary nerves, and, more important, of the vagus. All irritation of the vestibular nerve diffuses to these nuclei and creates a state of hyperexcitability: salivation is produced, and symptoms in the alimentary tract and in the heart. Nolt concludes that the final result is an exaggerated activity of the vagus following a vagotonic state, and that the victims of sea-sickness are to be found among the vagotonics, sympathicotonic being immune. Cazamian agrees with this explanation, and adds that the multiple peripheral excitations, reflected in the bulb, act on the two great nerves, the vagus and the sympathetic. He draws a parallel between the conditions in sea-sickness and those in shock and anaphylaxis. Sea-sickness being of vago-sympathetic pathology, atropine must be regarded as the main treatment. As a preventive, Cazamian injects 1/60 grain of neutral atropine sulphate, and as a curative 1/30 grain in males and 1/45 grain in females. If signs of intoxication appear, the drug is discontinued and stimulants administered. In predisposed subjects Nolt recommends the taking by the mouth of 1/60 grain of atropine sulphate, followed by two 1/120 grain doses at half-hourly intervals; in long voyages the patient is kept under the continued influence of the drug by taking 1/60 grain at the commencement and the two 1/120 grain doses afterwards. In cases that do not respond to atropine, an intramuscular injection of adrenaline may be tried. As adjuncts he mentions suggestion treatment, the wearing of a tight abdominal belt, and the recumbent position, to which Ichok adds incensement by repeated sea voyages and an exercise of will power.

### 

#### 

AS G. E. BINKLEY (*Amer. Journ. Surg.*, August, 1926, p. 87) points out, an early diagnosis of carcinoma in the terminal intestinal tract is of vital importance. Carcinoma of the rectum appears in all types and classes, and over 50 per cent. of cases occur in those between 40 and 60 years of age, men being affected twice as often as women. The onset of the disease is insidious, with some derangement of function of the alimentary canal such as flatulence and increased constipation; sometimes the onset is manifested by an attack of diarrhoea. Pelvic colon carcinomas are of slow growth, with a tendency to encircle the bowel and produce obstructive symptoms. The mid-rectum is the commonest site for carcinoma of the terminal intestinal tract. In these cases preliminary symptoms are few and are often overlooked till late. Constipation and the passage of blood are the cardinal signs. Abdominal examination in these cases reveals but little, and it is imperative to examine the rectum. Palpation frequently reveals a tumour mass, whilst the sigmoidoscope enables one to see higher up the bowel. X-rays are useful in high tumours, and it is often necessary to employ the barium enema. The diagnosis has to be considered between rectal cancer and diverticulitis, which is often preceded by the history of an inflammatory process. Benign tumours are usually attached by a pedicle. Blind fistulas and ulcerative strictures must also be considered. In doubtful cases a small section of tissue should be examined.

#### 

KIRSCHNER (*La Gynéc.*, July, 1926, p. 435) reports 10,000 cases of peritonitis and concludes that all cases of acute generalized peritonitis, except when of gonococcal or pneumococcal origin, should be operated on immediately. The result depends entirely on how soon after the onset operation is performed; a mortality of 24 per cent. after twelve hours rises to 66 per cent. after forty-eight hours. Death often results from shock on the day of the operation. The incision should, he thinks, be medial, and sufficiently long to permit search for and removal of the source of infection. He employs irrigation with physiological serum in diffuse peritonitis, and drying with compresses when the infection is limited. Medicated irrigations are said to be harmful and useless, but mechanical evacuation of the intestines should be practised. Drainage of the peritoneal cavity is inefficient; if all infective foci can be removed the wound should be closed without drainage, but if a limited haemorrhagic and necrotic area is left it is necessary to tampon and drain it with supple drains. Post-operative treatment should be directed to raising the tone of the capillaries, blood vessels.

and heart, and also the general resistance. The patient may assume the horizontal decubitus, or any other position preferred. Diuresis should be brought about by the rectal or intravenous administration of 1 to 1½ litres of serum containing salt or sugar; this should not exceed 400 calories a day. Vomiting can be controlled by lavage of the stomach. Finally, it is necessary to arouse intestinal action by every means; in cases of persistent paresis, enterostomy, and eventually multiple puncture of the intestine through the skin, will give surprisingly good results.

#### 454. Complications of Cholecystitis.

ACCORDING to J. B. DEAYER and V. G. BURDEN (*Annals of Surgery*, September, 1926, p. 379), cholecystitis usually begins as a chronic insidious process. Recognition of the early symptoms secures the best results with a minimum of risk. The acutely inflamed gall bladder should be removed, if possible, to get rid of the disease. Gangrenous cholecystitis is rare, as the gall bladder has a rich blood supply; perforation is therefore unusual. The symptoms resemble perforated peptic ulcer, and immediate operation is imperative. Calculi are usually the result of cholecystitis, and, when possible at the operation, the gall bladder should be removed. Pancreatitis is most often the sequel of cholecystitis, and the usual pathway of infection is through the lymphatics. In acute cases the pancreas is exposed through the gastro-colic omentum, and drainage is provided. In chronic pancreatitis removal of the gall bladder is better than draining it, since the focus of infection is abolished. The discovery of a stone in the common duct after cholecystectomy should be very rare, unless it has been overlooked at the original operation. Recurrence of symptoms following operations on the gall bladder may be due to (1) incomplete primary operation with failure to remove the diseased gall bladder or stone in the duct; (2) hepatitis and pancreatitis may persist for many months and then subside; (3) accidents at operation which injure the ducts and cause stricture and jaundice; (4) incorrect diagnosis before and during operation.

#### 455. The Growing Incidence of Cancer in Norway.

F. G. GADE (*Tidsskrift. f. d. Norske Lægeforening*, September 15th, 1926, p. 864) gives a summary of the findings of the Norwegian Committee for Cancer Research for the period July 1st, 1924, to June 30th, 1926. In the five-year period 1919 to 1923 there was a rise from 9.63 deaths per 10,000 in 1919 to 10.72 in 1923. There was a total of 14,128 cancer deaths in this five-year period—a cancer death rate of 10.74 per 10,000; it was as high as 11.38 per 10,000 in 1922. The cancer death rate in the period 1902 to 1912 was 9.33 per 10,000, and it will thus be seen that there has, apparently, been a considerable rise in the cancer death rate. Gade thinks that this apparent rise should be discounted to a certain extent on account of (1) the recent increase in the number of doctors in Norway, which assures a greater proportion of cancer diagnoses, and (2) the increased average expectation of life, resulting in an increased proportion of elderly persons in the community. Thus, in the interval between the decade 1881-90 and the decade 1911-20 the expectation of life for men increased by 6.89 years to 55.62, and for women by 7.51 to 58.71 years. In the five-year period 1919 to 1923 as great a proportion as 66.59 per cent. of all the malignant growths were situated in the digestive tract, and 51.66 per cent. in the stomach. The female reproductive organs were the seat of malignant disease in 12.07 per cent., and the prostate in 1.48 per cent. In 5.49 per cent. of all the cases of malignant disease the growths were sarcomas.

## Therapeutics.

#### 456. The Action and Clinical Use of Ephedrine.

As an alternative to adrenaline in certain conditions K. K. CHEN and C. F. SCHMIDT (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 836) recommend ephedrine, which is an alkaloidal principle of the *helvetica* variety of *Ephedra vulgaris*, which the Chinese have used for many centuries as a diaphoretic, circulatory stimulant, antipyretic, and sedative in cough. The authors state that ephedrine has a definite depressant action on the heart in large doses, or when the heart is under unfavourable conditions; and that its advantages over adrenaline are its more prolonged action, its low toxicity, its effective absorption from the intestinal tract, its easy isolation, the absence of habit formation, and its stability in solutions, even after boiling, or exposure to light and air for as long as nine months. Its stimulant action on the sympathetic central nervous system and its depressing effect on the heart may produce untoward results; stimulation of the sympathetic fibres in the kidney may cause albuminuria, stimulation of the central nervous system may

give rise to insomnia, nausea, and tremors, and a depression of the heart may set up arrhythmia or possibly heart failure, though so far this has not been reported. Clinical trials of ephedrine indicate that it will be found most useful as a local application to the nose in cases of chronic congestion, as in hypertrophic rhinitis and hay fever. Almost equally promising are its effects in asthma, and it has been used successfully as a mydriatic. As a circulatory stimulant ephedrine has proved disappointing, its lack of effect being due to its inability to cause appreciable stimulation of the vasomotor system and its tendency to depress the heart. It should not be injected intravenously in cases of profound shock, as it may do harm. The authors add that ephedrine may be advantageously administered with adrenaline to prolong the effect of the stronger stimulant; it may prove valuable in the treatment of anaphylaxis and urticaria, and as a respiratory stimulant in poisoning by narcotic drugs. It seems to be more regularly effective and less dangerous than any other single drug in experimental morphine poisoning.

#### 457. Emetine Periodide in Schistosomiasis.

R. M. GORDON (*Ann. Trop. Med. and Parasitol.*, August 13th, 1926, p. 229) reports on the oral administration of emetine periodide in dealing with infections by *Schistosoma haematobium* among West African children. The usual method of treatment hitherto has consisted of hypodermic injections of emetine hydrochloride subcutaneously, intramuscularly, or intravenously, until all the symptoms have disappeared and live eggs are no longer passed in the urine. The injections are continued for a variable period after this in order to prevent relapse. This method of treatment has certain objections in that the native strongly dislikes injections, and since the course is, of necessity, a long one, few patients can be persuaded to complete the series. Moreover, in several of the control cases in which injections were used by Gordon "emetine nodules" developed, together with sore arms, as a result of fifteen days of consecutive injections; one child showed alarming signs of heart failure. The oral administration of emetine periodide is stated to be free from these objections. The West African native is fond of taking medicine, and amongst a total of 630 doses given by the month vomiting occurred only once. Gordon selected 28 children, aged between 6 and 13; 14 of these were given daily injections of emetine hydrochloride for fifteen days, and all had ceased to pass live ova in the urine at the end of twenty-one days of observation. Of the other 14 treated by emetine periodide given orally for fifteen days, 12 of these had ceased to pass live ova at the end of the same period, while the remaining two were passing a mixture of dead and live ova. Gordon suggests that since the urinary findings continued to improve after the administration of the drug had ceased, it is probable that if the period of observation had been longer these two cases might also have become negative. He concludes that the oral administration of emetine periodide clears up the urine of children intensely infected with *Schistosoma haematobium* as quickly and with almost as great certainty as subcutaneous injections of emetine hydrochloride, but without the risk of ill effects. Further, the absence of unpleasant symptoms suggests that a larger dose of emetine periodide might be used if required.

#### 458. Iodine in Scarlet Fever.

H. J. NOVACK (*Med. Journ. and Record*, September 1st, 1926, p. 267) reports the results of a comparative study of 200 cases of scarlet fever treated with colodine—a 10 per cent. colloidal form of iodine. Full dosage consisted of 1 drachm every fifteen minutes to an hour up to eight doses on the first day, every hour to two hours up to eight doses on the second day, every two or three hours up to eight doses on the third day, four times on the fourth day, three times on the fifth day, and twice a day on the sixth day and to the end of treatment. No toxic phenomena or kidney complications resulted, and signs of kidney irritation prior to administration cleared up rapidly and completely; patients so treated appeared to tolerate the infection better and to be much less toxic. Complications were few and slight in cases treated early, the drug appearing to increase resistance to infection. When the treatment was commenced early a mild reaction followed, as evidenced by slight accentuation of the rash and fever and enlargement of the tonsils and glands. All these symptoms subsided in a few days, and a continuation of the treatment in moderate doses cleared up the case. When started later with complications already present a more marked reaction resulted in which every symptom was accentuated; this was followed by gradual subsidence on reduced doses after a few days of intensive medication. The average duration of stay in hospital was found to be greatly reduced, and Novack considers that colodine is of considerable value in the specific treatment of scarlet fever with or without combined serum treatment in severe cases.

authors attribute this to the absence in old age of depressant substances elaborated by the ovaries and passed into the blood stream. These circulatory disturbances are often not very pronounced, but slight oedema, albuminuria, varicose veins, and arterial hypertension are all indications of cardiovascular derangement, appropriate treatment of which will stop the uterine haemorrhage. Sometimes metrorrhagia is associated with syphilitic changes in the blood vessels and can be cured by specific treatment. The author strongly recommends a complete clinical examination of both the central and peripheral circulation in all cases of metrorrhagia occurring after the menopause.

#### 464. Post-puerperal Morbidity.

H. A. MILLER (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 830) presents a statistical study of 1,000 cases of post-puerperal women, the examinations having been made as soon as possible after the child was six weeks old. He finds that post-puerperal morbidity occurs much more frequently than is generally supposed. Operative intervention in labour of any character seems to increase post-puerperal morbidity, and, even ignoring the immediate danger of infection, is to be condemned, except where absolutely necessary to preserve the life of mother or child. Pyrexia during the puerperal period, even though slight, leaves in its wake some definite evidence of injury having been done. The present post-puerperal morbidity would seem to justify a return to rational non-intervention in the normal woman and the avoidance of all measures to hasten delivery, except in the presence of foetal distress, uterine inertia, or disproportion. Attention to cervical injuries will markedly lessen the discomfort of the patient, and in cases of erosion may have an influence on decreasing the incidence of malignancy. Post-puerperal examinations should invariably be made.

#### 465. Induction of Labour per Rectum.

P. KLEIN (*Zentralbl. f. Gynäk.*, September 25th, 1926, p. 2493) has observed over 800 cases of induction by this method in five years. The procedure consists of the insertion into the rectum of a balloon filled with water; it acts by stimulating Frankenhäuser's ganglia by pressure, and more effectively than if placed in the vagina. The chief advantage is the lessened risk of sepsis. The balloon in the rectum assists the flow of secretion from the vagina by flattening the posterior fornix and emptying out the accumulated secretions, thus lessening the risk of their infection. Further, the balloon stretches the vaginal outlet by pressure and dilates the cervix in cases where other means had been tried unsuccessfully. It causes no discomfort or unduly severe labour pains, but surprisingly quick dilatation, followed shortly by strong pains; it is therefore useful in elderly primiparae, in premature rupture of the membranes with weak pains, protracted labour with rising temperature, purulent discharge, and inflammatory conditions of the vagina or external genitals. Klein uses Barnes's balloon, which is passed up to the utero-sacral ligament and filled with about five ounces of water at 113° F., the warmth giving additional stimulus to the paracervical ganglia. It is retained not longer than six to eight hours, three to four hours often being enough. It can be reinserted if unsuccessful or the pains weak. Its use is inadvisable in uterine hypoplasia, or where the contractility of the muscle has been impaired by hydramnios, old-standing metritis, or sepsis. With obstinately weak pains it does well if associated with one of the chemical methods, such as quinine.

## Pathology.

#### 466. Histology of Amyotrophic Lateral Sclerosis.

F. J. WARNER (*Journ. of Nerv. and Ment. Dis.*, September, 1926, p. 229) quotes Hassin as finding in amyotrophic lateral sclerosis marked cell destruction, neuronophagic phenomena, chromatolysis, and disappearance of the Betz cells; the changes, more or less marked in the motor ganglion cells, were absent in the sensory ganglion. Alzheimer found, in a case of progressive muscular atrophy, cell changes, not only in the anterior horns, but also in the medulla and motor cortex, while in bulbar paralysis marked degeneration of the motor nuclei of the medulla was associated with those of the motor cortex and the anterior horn cells. Warner believes, therefore, that the changes in amyotrophic lateral sclerosis, bulbar paralysis, and progressive muscular atrophy are essentially of the same character, differing in the intensity of the involvement of certain areas. The author describes his findings in a case of amyotrophic lateral sclerosis, showing spastic gait, marked atrophy of the extremities, and fibrillary twitches in the muscles of the chest, upper extremities, and tongue. The cranial nerves were normal, and the uvula, soft palate, and pharynx showed no abnormality. Tendon

reflexes of the upper and lower extremities were exaggerated and the signs of Babinski and Romberg were absent, but ankle clonus was present, as also was knee clonus; the abdominal and cremasteric reflexes were present but diminished; the thoracic, abdominal, and genito-urinary organs were healthy and cutaneous sensation was normal. Warner summarizes his histopathological findings as follows: (1) Reactive pia-arachnoid changes; (2) marked degenerative changes in the cells of the anterior horns of the spinal cord, motor nuclei of the bulbus, and to a lesser extent in the motor area of the cortex, with practically none in the occipital, temporal, and frontal lobes, or in the posterior horns of the spinal cord; (3) marked degenerative phenomena of some pyramidal tract fibres; (4) accumulation of lipoids in the adventitious spaces of the blood vessels of the entire central nervous system, and especially in the areas of the pyramidal tract fibres; and (5) absence of inflammatory phenomena. The author draws attention to the pronounced spastic phenomena with rather mild pyramidal destruction, and the absence of the Betz cells; he concludes that the process was much more marked in the spinal cord, began as a progressive muscular atrophy, and, successively involving other motor elements, resulted in amyotrophic lateral sclerosis. He believes that, if the involvement of certain motor elements is especially marked in the anterior horns of the spinal cord, progressive muscular atrophy follows; if in the medulla, bulbar paralysis is produced; and if the motor area of the cortex is also involved, the picture of amyotrophic lateral sclerosis results.

#### 467. Etiology of Scarlet Fever.

C. NICOLLE, E. CONSEIL, and P. DURAND (*Arch. de l'Inst. Pasteur de Tunis*, September, 1926, p. 229), after investigations extending over twelve years, report that the inoculation of a virus produced in the tonsil of a patient with scarlet fever into the tonsil of a healthy individual not previously proved to be susceptible, caused a scarlet fever angina and glossitis with typical fever, but without rash or subsequent desquamation. When the fourth subculture of the streptococcus isolated from the tonsil of the same patient was planted on that of a healthy individual of known susceptibility, typical scarlet fever, with fever, angina, glossitis, rash, and desquamation, was produced. The subcutaneous injection of non-filtered urine from the same patient into a susceptible subject gave rise to two attacks of a toxic scarlatinal erythema, separated by a day and lasting for some hours, the first being only febrile. The same urine, filtered, gave a clear Dick reaction in two individuals later shown to be susceptible. The streptococcus which produced the symptoms of scarlet fever possessed haemolytic and toxic properties, and did not ferment mannite. The authors agree that their experiments confirm the work of the Dicks, and prove that the causative agent of scarlet fever is a streptococcus.

#### 468. Anaphylaxis in Bronchial Asthma and Pulmonary Tuberculosis.

H. GROSSFELD (*Wien. Arch. f. Innere Med.*, September 1st, 1926, p. 117), as the result of clinical observation of 215 cases of bronchial asthma, has come to the conclusion that the of bronchial asthma are of tuberculous origin. Tuberculous attack is an anaphylactic reaction in the blood of a bacterial derived from the proteins of the tubercle bacilli. It has been shown by experiments that when animals have been infected with human tuberculosis a typical attack of asthma may be induced by an injection of tuberculin. In every case there was a definite anaphylactic reaction. In cases of genuine bronchial asthma a venous hyperaemia and stasis of the circulation in the bronchial veins occurs. Grossfeld thinks that this may be regarded as a protective or "defence" reaction against the tuberculous invasion, and that it affords an explanation of the apparent discrepancy in the records of various observers, some of whom believe there is an antagonism between asthma and tuberculosis, while others have noted a frequent coincidence of the two diseases. The heterogeneous factors that determine the onset of the attacks of asthma are considered by Grossfeld to be chiefly non-specific external or internal irritants, but in tuberculous patients an endogenous antigen may be produced by a transient disintegration of tubercle bacilli, thus evoking an anaphylactic reaction. Changes in the endocrine secretions may occur in cases of chronic tuberculosis, due to the interaction of katabolic products derived from the breaking up of tubercle bacilli. It was found that these disturbances of endocrine equilibrium produced a definite hypo-adrenalinaemia, and it appeared also that in tuberculous patients a definite albumin-antialbumin reaction might occur. The author thinks it probable that in two of his cases inhalation of dust from the same source caused, in one case, pulmonary tuberculosis, and in the other bronchial asthma.

# 

### Medicine.

#### 468. Hypoglycaemic Reactions during Insulin Treatment.

A. V. GREAVES (*Med. Journ. and Record*, August 18th, 1926, p. 203) describes a hypoglycaemic attack in a patient who, after being taught to select, calculate the value of, and weigh his diet, test his urine, and attend to his treatment, became careless after passing from medical control. The symptoms exhibited were breathing of the Kussmaul type, breath heavy with acetone, marked drowsiness verging on coma, beefy red tongue, dry cracked lips, oedema of the face, pitting over both tibiae, pulse of 110, but a normal temperature. Greaves believes that the initial coma was due to the supervention of an infection (an acute cold or influenza) in addition to careless dieting, with a consequent marked loss of carbohydrate tolerance, the later state of hypoglycaemia being due to the sudden development of immunity to the infection, with equally sudden regaining of a high level tolerance. He finds that in marked diabetes with high blood sugar levels the elevation of temperature usual in infections is absent, and so the infection escapes detection; the pulse rate, however, increases commensurately with the infection. The deduction is that in grave diabetic crises the frequency of the pulse rate rather than the degree of pyrexia should be taken as indicating infection; increased carbohydrate tolerance may follow closely on the subsidence of infection. Close attention should be paid therefore to such patients, if on high insulin dosage, in view of the possible occurrence of sudden hypoglycaemia consequent on the subsidence of an infective process.

#### 470. Diagnosis of Diabetes.

E. S. DU BRAY (*Journ. Lab. and Clin. Med.*, August, 1926, p. 1915) emphasizes the practical importance of diagnosing early cases of diabetes by routine blood examinations and determination of the blood sugar in the fasting state. In latent cases, which he thinks are very common, the glucose tolerance test gives valuable information not otherwise obtainable. The estimation of the blood sugar alone in a fasting patient is found to be sometimes insufficient for diagnostic purposes, since a patient with severe diabetes may give a normal fasting blood sugar reaction if dieted immediately before the test. Bray adds that glycosuria in itself can no longer be regarded as a sign of a single disease; it appears more rational to think of it as a symptom like jaundice and headache. The diagnosis of renal glycosuria should not be too easily made, since unquestionable instances of this condition are uncommon, and few cases have been followed for a sufficient period for the final outcome to be seen. An elevation of the renal threshold occurs from time to time in diabetic patients who have been treated with insulin, so that hyperglycaemia exists without glycosuria, and a constant elevation of the threshold appears to be a disadvantage because of the excessive work continuously thrown upon the internal secretion of the pancreas. Non-diabetic glycosurias associated with elevated blood sugar content include the alimentary, neurogenic, toxic, and endocrine groups. The last group comprises a large and poorly understood number of cases in which there is an associated disturbance of function of the glands of internal secretion. The outstanding example is the diminished carbohydrate tolerance of hyperthyroidism. The glycosurias in pituitary and adrenal disturbances need further experimental study. True pancreatic diabetes presents a primary diagnostic difficulty in cases of asymptomatic glycosuria in patients complaining of the complications of diabetes only, and in patients first seen in coma.

#### 471. The Aorta in Malaria.

E. BENHAMOU (*Ann. de Méd.*, August, 1926, p. 145) reviews the literature and records his observations on the heart in malaria as the result of serial radioscopies. His conclusions are as follows. (1) There is a characteristic malarial condition of the aorta which develops earlier when the malarial paroxysms are repeated and violent. It is essentially a dilatation, with a regular outline, and, normally, a grey colour; the dilatation, which is usually moderate, remains localized to the first part of the aorta. Though very common, it is generally latent, and systematic examination with the screen is required for its detection. It constitutes a true stigma of relapsing chronic malaria which has received little or no treatment. (2) When the febrile attacks are allowed to run their course an increase of dilatation may be seen on the

screen, though the regular contour and normal colour of the aorta are preserved. As soon as energetic treatment is instituted the aorta becomes progressively smaller. (3) The aorta in malarial patients undergoes movements of dilatation or contraction at the same time as the heart. (4) The principal symptoms are pain and dyspnoea. The pain, which is rather a feeling of retrosternal discomfort, does not radiate into the left arm, but is accompanied by anxiety and not by the sensation of imminent death. Dyspnoea, which is often wrongly attributed to anaemia, is a more frequent symptom. (5) Physical examination reveals suprasternal pulsation, increase of the aortic dullness, and a soft systolic murmur, very different from the harsh systolic murmur of chronic aortitis. The characteristic feature of the murmur is its variability; it disappears after intensive quinine treatment, reappears during a relapse, and finally is no longer heard. (6) This dilatation of the aorta does not indicate aortitis, at least at the outset and in the great majority of cases; pathological studies show either no change or else the lesions of concurrent syphilis. Moreover, in experimental malaria in long-standing carriers no changes are found in the aorta. According to Benhamou the dilatation is functional and is the result of hypotonicity. (7) Treatment consists in intramuscular injection of quinine as long as the dilatation persists, associated with digitalin or adrenaline.

#### 472. Etiology of Nasal Catarrh.

D. F. SMILEY (*Amer. Journ. of Hygiene*, September, 1926, p. 621) has collected the records of respiratory infections amongst 4,000 male university students for twelve years. These he has compared with the daily temperature, rainfall, and hours of sunshine. The highest incidence of respiratory diseases occurred in December, January, February, or March—most frequently in January. No definite relation was apparent between the incidence of respiratory disease and the rainfall, but there was a reciprocal relation between disease and the temperature and sunshine curves. Thus the lower the temperature and the less the sunshine, the greater was the incidence of colds and other diseases of the respiratory tract; the higher the temperature and the greater the amount of sunshine, the less was the incidence of colds. The author thinks that these facts suggest that colds are due to an interference with the vitamin metabolism of the body which leads to a diminution of resistance against bacterial infection.

### Surgery.

#### 473. Treatment of Cutaneous Cancer.

A. P. MISSORICI (*Arch. Ital. di Otol.*, August, 1926, p. 418) reviews the methods of treatment of carcinoma of the skin, and especially as it occurs in the face. He states that by radium therapy a number of cases of skin cancer have been definitely cured. The rodent ulcer or basal-celled carcinoma responds very readily to treatment by radium, but a very considerable number of cutaneous epitheliomas are not cured by this treatment. Electro-coagulation or diathermy is not very suitable on the skin, especially of the face, on account of the very considerable loss of tissue involved. A number of chemical agents have been tried, including chromic acid, methylene blue, and methyl violet, but the author found that arsenious acid gave the best results. He has tried various strengths and solvents, and reports that a suspension of anhydrous arsenious acid in a mixture of equal parts of alcohol and ether gave the best results. He considered that it was better to use a somewhat stronger suspension than some other writers had advised. All crusts and discharge are removed from the surface of the cancer and the suspension is applied and left for three to four days. At the end of that time the dressing is removed, all sloughs cut away, and a new dressing applied; this is repeated every four days. It is found advisable to increase gradually the strength of the arsenious acid in suspension from 1 to 10 per cent., which latter strength is applied in the form of a paste. Missorici found that by using a mixture of alcohol and ether a better penetration into the deeper layers of the skin was obtained when alcohol alone was used. The treatment is continued until induration has disappeared and the skin has healed over. A soft, hardly noticeable scar remains, and this result is usually obtained in from fifty to a hundred days, except in very advanced cases. The author records seventeen cases of cure in which there has been no recurrence for periods up to two and a half years.

## 474.

## Facial Boils.

R. DEMEL and A. HEINDL (*Deut. Zeit. f. Chir.*, October, 1926, p. 379) state that every case of facial boils should be regarded as serious and treated from the first with proper care. The cases must be distinguished not only by the situation of the lesions but also, and chiefly, by the accompanying symptoms. In mild forms, which constitute the majority of cases, good results may be obtained by strictly conservative treatment, such as the application of gauze smeared with an ointment of lanoline and 10 per cent. zinc oxide, or by compresses of 96 per cent. alcohol. Incision or cauterization is not indicated until an abscess has formed. In malignant cases which are characterized by progressive inflammation, induration of the surrounding tissue, and the formation of hard cords indicating thrombophlebitis accompanied by symptoms of septicaemia, active and radical treatment is required. The statistics of Professor Eiselsberg's surgical clinic at Vienna during the last seven years show that there has been a steady increase in the number of cases treated by conservative measures. Thus, during the period 1919-20, 136 cases, including 15 boils of the upper lip, which is the most serious localization, were treated by operation, and 117 cases, including 10 boils of the upper lip, were treated by conservative measures. During the years 1924-25 only 49 cases, in none of which the upper lip was affected, were operated on, while 295, including 21 boils of the upper lip, received conservative treatment only. In 31 of the 49 cases the operation was limited to simple application of the platinum cautery or removal of the suppurative focus.

## 475.

## Recurrent Cancer of the Penis.

FROM six cases of cancer of the penis seen in three years, G. JEANNENEY (*Journ. Méd. de Bordeaux*, September 10th to 25th, 1926, p. 693) reports one case with recurrence. The patient, aged 62, had an attack of gonorrhoea when 18, since when there had been a "morning drop" and slight difficulty of micturition. A pimple the size of a pin's head appeared on the glans twenty-two years later and was cauterized. This cauterization was followed by a rapid recurrence, and amputation of the glans was performed, a part of the prepuce being left, and the glands being untreated. Ten years after this the patient noticed an infiltration at the end of the penis and an induration of the prepuce, with pain on micturition and erection. In February of this year—that is, thirty-two years after the amputation—the conditions were that the prepuce was indurated, infiltrated, deeply adherent, and covered with ulcerated discharging red vegetations. The inguinal glands on both sides were affected. The penis was now amputated at the root, and the glands on each side were curetted with the thermo-cautery; those at the base of Scarpa's triangles and some vertical to the thighs were dissected out. The final results were good. Microscopically, sections showed only a marked hyperplasia with no evidence of malignity. Jeanneney draws attention to the slow development of the recurrence, and the folly of speaking of cure in cancer. Despite this slow evolution and the rarity of gland involvement, he maintains that cancer of the penis follows the general law of cancer, and that complete excision of the organ and neighbouring glands should be performed as in cancer of the tongue. The gland excision is best done rapidly with the thermo-cautery, there being with this method less danger of sepsis.

## 476.

## Gastric Ulcer and Carcinoma.

J. S. LAWRENCE and A. V. BOCK (*Boston Med. and Surg. Journ.*, September 30th, 1926, p. 651) discuss the relation between gastric ulcer and carcinoma, based on a study of 98 cases of carcinoma and 48 cases of ulcer, the majority of which were confirmed by operation and an appreciable number further confirmed by pathological examination. A comparison of the clinical findings of the two conditions showed that most of the ulcer cases had their initial symptoms about twenty years earlier than the majority of those with carcinoma, and on the basis of duration of symptoms 10 per cent. is stated to be a high value to give to cases of ulcer which later became malignant. A good appetite was noted about twice as frequently in the subjects of ulcer as with those with cancer, and loss of weight was found to be much more rapid in malignancy than in ulcer. In cancer the absence of free hydrochloric acid in the gastric contents was much more common than in ulcer, and occult blood was found about three times as often in the stools of cancer cases as in patients with ulcer. Over half the cancer cases presented a palpable abdominal mass; this was present in only one of the ulcer cases. Epigastric pain was the most common initial symptom in both classes of cases. The authors conclude that these definite differences in the clinical findings show that there is no very close relation between the two conditions. They hold that patients of cancer age with unexplained gas in the stomach, heartburn, or constipation should be x-rayed at once.

## Therapeutics.

## 477. Serum Treatment of Cerebro-spinal Fever.

J. SIEGL and K. SOLLGRUBER (*Arch. f. Kinderheilk.*, August 7th, 1926, p. 1) record four cases of cerebro-spinal fever in children aged from 7 months to 5½ years in whom Hamburger's method was employed, whereby not only larger quantities of serum were administered, but the serum was brought from the spinal canal into the inside of the skull. The method, which is very simple and requires no apparatus, consists essentially in gradual replacement of the cerebro-spinal fluid by air and substitution of antimeningococcal serum in its place. The technique is as follows: Lumbar puncture is performed in the ordinary way, and the spinal fluid is allowed to escape until an ordinary pressure is reached. Air is next insufflated with a 10 c.cm. syringe; after waiting for a few seconds until the air has had time to rise in the spinal canal an equivalent amount of fluid is withdrawn. This process is continued as long as any fluid can be removed. The patient is then put in a position with the head lower than the site of puncture, and repeated syringefuls of warmed serum are injected, the excess of air being removed with the syringe in proportion to the amount of serum injected. This process is continued as long as any air can be aspirated. The replacement of the cerebro-spinal fluid by air was always well borne by the children and no alarming symptoms were ever observed.

## 478. Therapeutical Scope of Ultra-violet Radiation.

M. BAVELAËR (*Journ. de Méd. et de Chir.*, September 10th, 1926, p. 609) cites the following ways in which ultra-violet rays have proved efficacious. (1) Acting on the skin it causes hyperaemia, pigmentation, excitation of defensive and reparative processes (valuable in the treatment of sores and cutaneous affections), and regulation of the glandular secretions. (2) Its action on the blood is very marked in cases in which certain of the blood elements are deficient. The amount of haemoglobin and the number of erythrocytes is increased in anaemia; there is an increase in the calcium and phosphorus content of the blood, where this is decreased, as in rickets. The number of leucocytes is also increased, and arterial tension is lowered in cases of hypertension. (3) Its action on the tissues is particularly marked in the bones, where there is an improvement in growth, and in the defensive and reparative processes, especially in tuberculous osteitis. Exposure to the rays improves the tonicity of the muscles. (4) Acting on the internal secretory glands the rays stimulate the activity, chiefly of the ovaries, thyroid, parathyroids, and thymus. (5) The action on the nervous system is variable, depending on the dose, and chiefly on the sensitiveness of the patient. In general the action is stimulating, and may cause excitement and insomnia, which may be avoided by commencing treatment with weak doses. The best results of treatment are, Bavelaër adds, obtained in children, especially in cases of dystrophy, spasmodophilia, and rickets. Bavelaër maintains that contraindications are practically negligible if the rays are administered in therapeutic doses, and that treatment is remarkably safe. He advocates sufficiently long exposures given discontinuously, and states that continuous and very prolonged treatment is inadvisable. The choice of apparatus, dosage and its progression, the length of the exposures, their timing, and the interval between each, and the total duration of the treatment are essential parts of the skilful administration of the rays.

479. E. I. WYMAN (*Boston Med. and Surg. Journ.*, August 26th, 1926, p. 396) finds that the climate of New England is unsuitable for natural heliotherapy, except during the summer, and uses lamps in his hospital practice. He states that patients whose skins are unusually susceptible should receive short spells of treatment several times a day, and that many dark-skinned patients can bear double the length of exposure which is the maximum for blonds. Ultra-violet rays are of great value in cases of rickets, spasmodophilia (tetany), tuberculosis, and of various skin diseases. The endowment with antirachitic power of various animal and vegetable oils by exposure to radiation from a mercury vapour quartz lamp is stated to be due to activation of cholesterol in animal foods and of phytosterol in vegetables. In rickets Wyman gives cod-liver oil in addition to ultra-violet light treatment; treatment is continued until all rachitic symptoms have disappeared. In spasmodophilia with its low calcium content in the blood plasma, ultra-violet therapy not only relieved the symptoms, but the calcium content rose to normal. The author gives 10 to 20 grains of calcium chloride thrice daily in addition to the ultra-violet irradiation. After cessation of heliotherapy in rickets the administration of cod-liver oil is continued to prevent recurrence of rickets; and calcium chloride is given for prophylaxis against tetany.

The time required to cure the average case varied from ten to fourteen days. Wyman found that ultra-violet rays were of decided value in the treatment of peritonsillar, glandular, and osseous tuberculosis. Of the glandular forms, the mesenteric was the most rapidly improved, then the mediastinal, and lastly the peripheral forms. Cases of millary pulmonary tuberculosis did not improve, although treated in an early stage. Ultra-violet radiation appeared to improve the general condition in mediastinal and mesenteric adenitis and to relieve such symptoms as cough in the former and abdominal pain in the latter condition; early calcification of infected glands was observed. In tuberculous peritonitis the results were variable, but ultra-violet therapy seemed to be useful in a few cases. The author adds that all cases of peritonitis showed definite improvement while under treatment. Favourable results were observed in some cases of chronic furunculosis, which had not cleared up with vaccine and local therapy; it has also been beneficial in some cases of bronchial asthma.

#### 440. Nicolle's Vaccine in the Treatment of Soft Chancre.

KRIKORIAN (*Paris Méd.*, October 9th, 1926, p. 255) recommends for the treatment of soft chancre the use of Nicolle's vaccine prepared from the bacillus of Dancery and injected intravenously in doses of 200 to 700 millions. With subcutaneous injections there is said to be risk of causing soft-chancere-like lesions at the point of inoculation. Krikorian states that good effects are quickly produced on the chancre and also on its complications; failures are often due to an incomplete treatment in cases of exceptional virulence of the organism. The only drawback to this method of vaccine therapy is the violent general reaction, which comes on about two hours after the injection and is characterized by rigors, slight pyrexia, and sometimes vomiting. This reaction appears after each injection; it is very violent after the first one, lasts from twelve hours to three days, and the patient is unable to work for twenty-four hours. After the subsequent injections the reactions are less marked and last only five or six hours. No other untoward symptoms have so far been reported, and Krikorian holds that this severe reaction is of secondary importance in view of the excellent results obtained.

## Anaesthetics.

#### 481. The Surgical Value of Carbon Dioxide and Oxygen Anaesthesia.

C. N. CHIPMAN (*Anaesthesia and Analgesia*, August, 1926, p. 209) reports his experience of using one part of carbon dioxide to three of oxygen in place of nitrous oxide and oxygen as a preliminary anaesthetic in tonsil cases in adults. After six to ten inhalations the patient became unconscious, and the anaesthesia was continued by admitting ether to the mixing chamber; it was noticed that the induction of anaesthesia was more rapid than by other methods, and that there was an absence of resistance or struggling. An apparent decrease in the amount of haemorrhage was observed, the blood clotting more quickly and firmly, and thus necessitating the use of fewer sponges and sutures than in the case of other anaesthetics. In a series of twenty cases it was found that the average coagulation time, taken before and during operation, was reduced by about one-half, and similar results were noted in ten cases where the coagulation time was fifteen or twenty minutes after the tonsils had been removed. Two hours after operation the coagulation times were found to be about the same as those before operation. The longer the coagulation time before operation the greater was the reduction produced by this method. Of 213 patients with an average coagulation time of 4.3 minutes the average reduction was 2.32 minutes after using one part of carbon dioxide to three of oxygen—giving an average time of 1.98 minutes. Chipman considers that the excessive amount of oxygen view is responsible for this reduction in coagulation time; his view is supported by the fact that less bleeding followed tonsillectomies under nitrous oxide and oxygen than under ether anaesthesia.

#### 482. Posture with Reference to General Anaesthesia.

W. MEYER (*Amer. Journ. Surg.*, August, 1926, p. 63) discusses the importance of posture during and immediately after operations under general anaesthesia, with special reference to the prevention of aspiration of the gastric contents, which, as he remarks, may give rise to acute infectious bronchitis, the necrosis of the lung and more pulmonary abscesses, and even sizes the importance of the commencement of a spell of vomiting being immediately treated by the adoption of the

Trendelenburg position, with the head turned well to one side, so that the fluid can escape at the lower angle of the mouth and be prevented from entering the lungs. He mentions the anaesthetic procedure of T. L. Bennett, who performs gastric lavage through a stomach tube towards the end of an operation, the stomach being completely emptied subsequently. Meyer recommends that on the stretcher after the operation, and in bed, Sims's position should be adopted in order to prevent aspiration. The author adds that the adoption of a modified Trendelenburg position during after-treatment in bed may prevent femoral thrombosis and subsequent pulmonary embolism. Blocks are placed beneath the lower end of the bed to raise the lower limbs, and the upper part of the body is elevated so as to avoid inconvenience to the patient. Since adopting this posture he has not encountered thrombosis of the femoral vein.

#### 483. Ethylene Anaesthesia in Obstetrics.

J. KUEBELMAN and H. F. KANE (*Surg., Gynecol. and Obstet.*, September, 1926, p. 389) record their observations on 85 obstetrical cases in which they employed ethylene as an anaesthetic. Of these, 33 were delivered spontaneously, 23 by low forceps, 9 by mid forceps, 6 by podalic version, and 14 by Caesarean section; 53 patients were primiparae, 25 were 2-parae, and 7 were 3-parae. The results were as follows: complete analgesia was obtained in 84 per cent., appreciable relief in 15 per cent., and there was failure in only 3 per cent. Progress during the second stage of labour seemed to be more rapid. No harmful effects on the child were noted. Podalic version was easily performed under ethylene anaesthesia. Ethylene appeared to be the ideal anaesthetic for Caesarean section. Its efficacy seemed to be increased by the use of morphine in the first stage. The authors add that ethylene is of value in the second stage of labour because it rapidly induces analgesia and anaesthesia; its action is fleeting, and there are no latent ill effects on the mother or child.

#### 484. Prolongation of Local Anaesthesia.

G. DE TAKATS (*Surg., Gynecol. and Obstet.*, July, 1926, p. 100) states that a combination of tutocain—a synthetic derivative of an amino alcohol—with 0.1 per cent. solution of eucupin (is-amylihydrocuprein) and the usual dose of adrenaline causes a post-operative analgesia of about twenty-four hours. This combination of tutocain and eucupin is soluble in water, can be sterilized, does not counteract adrenaline, and is not toxic in the quantities stated. It does not cause any tissue reaction, or any disturbance in wound healing, as shown by intracutaneous tests, microscopical sections, and a hundred operations performed with this solution. Tutocain was used in a 0.2 per cent. dilution to replace 0.5 per cent. novocain, and 0.5 per cent. tutocain instead of 1 per cent. novocain, because the dermal wheals, especially with the addition of adrenaline, were found to produce longer anaesthesia. An anaesthesia lasting longer than twenty-four hours was not considered desirable owing to the possibility of trophic disturbance.

## Obstetrics and Gynaecology.

#### 485. Uterine Myoma and Pregnancy.

P. FIRKET (*La Gynéc.*, June, 1926, p. 359) records two cases illustrating the tolerance of intervention which is sometimes shown by the pregnant myomatous uterus. In the first, shown by the pregnant myomatous uterus. In the first, a primipara, aged 33, three months pregnant, complained of pain in the left groin, and was found to have a hard rounded tumour, apparently separated by a groove from the uterus, in the left fornix. The tumour, regarded as an incarcerated ovarian cyst, was found at operation to be an intramural myoma of the left cornual region; after its removal by enucleation pregnancy continued to term. The second case was that of a primipara, aged 30, who suffered from severe vomiting at the fourth month. A fluctuating rounded tumour was palpable in the pouch of Douglas and was regarded as anaesthetic. Later the vomiting reappeared, and at the sixth month a large tender swelling was noted to one side of the body of the uterus. At operation this swelling, which was twice the size of the first, was suspected to be a sarcoma, and hysterectomy was performed; it proved, however, to be a necrobiotic myoma containing 150 c.cm. of fluid.

#### 486. Gonococcal Abscess in the Wall of the Uterus.

H. A. COLE (*Kenya Med. Journ.*, September, 1926, p. 171) reports a case of gonococcal uterine abscess in an intelligent native woman, married, with two children. The patient gave no history of an attack of gonorrhoea or discharge, nor was there any interference with the menstrual function with

the exception of three months' menorrhagia or dysmenorrhoea. Five months before being treated she began to feel unwell and noticed a gradual increase in the size of her abdomen, simulating pregnancy. Laparotomy was performed, and on incising the peritoneum a mass, containing the ovaries and tubes, was found; contiguous with it anteriorly was a small swelling which proved to be the uterus, and it was apparent that the condition was one of pelvic infection with an abscess of the posterior uterine wall. About a pint of pus was evacuated, a drainage tube inserted, and the wound closed; the patient made an uneventful recovery. Slides of the pus showed gonococci, mostly extracellular. Cole presumes that one of two things must have happened: there must either have been an infection of the uterine muscular wall which gave rise to an abscess of low virulence, or an obstruction of the lumen of one or more compound racemose glands of the endometrium. He favours the first explanation because the mass of adhesions in the pelvis supports it, otherwise the abscess would have been expected to burst into the uterine cavity.

#### 487. Endometrioma of the Ovary.

D. DOUGAL (*Journ. Obstet. and Gynaecol. of the British Empire*, Autumn Number, 1926, p. 439) reports a case of endometrioma of one ovary in a patient, aged 32, from whom the other ovary and both Fallopian tubes had been removed eleven and a half years previously for bilateral salpingo-oophoritis. At the second operation the remaining ovary was found adherent to the uterus, near the cornu; it contained a large tarry cyst with endometrial tissue in part of its wall, a small dermoid containing hair, several follicular cysts, and one lutein cyst filled with blood. Endometrial tissue extended deeply into the wall of the cornu and into the ovary. Dougal rejects the possible explanation that endometrial tissue had already entered the ovary before the tubes were removed, or that one or other stump of the tubes had been left patent, so allowing endometrial fragments to escape into the peritoneum during menstruation. He concludes that the endometrioma must have extended directly from the uterine cavity to the ovary by infiltration of the intervening structures. Adenomyomas were present in both uterine cornua, strongly suggesting that the uterus was primarily responsible for the ovarian growth, and islands of endometrium were found in the tissues between the uterine cavity and the tarry cyst, indicating the process of infiltration. Dougal suggests, finally, that the commencement of endometrial proliferation may be attributable to preceding pelvic inflammation, which in this case was gonococcal.

#### 488. Prophylactic Use of Pituitary Extract in the Third Stage of Labour.

F. JESS (*Zentralbl. f. Gynäk.*, September 18th, 1926, p. 2440) strongly recommends the routine intravenous injection of pituitary extract in the third stage of labour, within five minutes of delivery of the child and before placental detachment has occurred. The preparation he employs is a German one, which has been stated to be less concentrated than those used in England. Comparing two series of 503 cases, in one of which pituitary extract had been injected in this way, he found that the interval between the birth of the foetus and the passage of the placenta was reduced by one-half, and the loss of blood was diminished by almost one-half in those patients injected. Replying to those who have criticized the method by citing cases of uterine atony with severe bleeding following the contraction brought about by the pituitary extract, Jess states that such untoward symptoms (which do occur in rare cases) can be controlled with ease by repeating the intravenous injection of pituitary extract, and at the same time administering a reliable ergot preparation intramuscularly. He recommends the joint use of pituitary extract and ergot in all cases in which it has been necessary to anaesthetize the patient with ethyl chloride, ether, or chloroform.

## Pathology.

#### 489. Viability of *B. acidophilus* and *B. bulgaricus* in the Human Intestine.

FURTHER evidence is submitted by W. L. KULP (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 833) that *B. acidophilus* can be recovered in large numbers from the faeces of persons ingesting the organism in the form of milk culture or milk suspensions, and that *B. bulgaricus*, when similarly administered, fails to appear in the faeces; he emphasizes certain clinical results of using *acidophilus* milk or milk suspensions. The chief criterion of *acidophilus* milk therapy is the clinical improvement of the patient. This has been explained as being due to the appearance of large numbers of *B. acidophilus* in the intestinal tract with

a corresponding decrease in toxin-forming bacteria; therefore, any marked clinical improvement should be associated with the appearance of large numbers of viable *B. acidophilus* in the faeces. Kulp's investigations lasted for two years and led him to the conclusion that all strains of *B. acidophilus* are not equally viable, and that therefore the strains used in treatment should be carefully investigated, first, with especial reference to fermentation reactions and their persistence in normal human subjects.

#### 490. Basal Metabolism in Diseases of the Endocrine Glands.

A. TARSITANO (*Il Morgagni*, September 12th, 1926, p. 1153) has made estimations of the basal metabolism in patients suffering from diseases of the endocrine glands. In six cases of hyperthyroidism the increase in the basal metabolism varied between 21 and 96 per cent., the degree being in proportion to the clinical severity of the disease. In one case of infantilism associated with insufficiency of the pituitary the basal metabolism at different examinations was from 20 to 30 per cent. below normal, and in a case of dystrophia adiposo-genitalis it was 16 per cent. below normal. In the latter case the author estimated the effect of food on the rate of metabolism. He gave the patient a meal consisting of 200 grams of roast veal, 100 grams of bread, 40 grams of sugar, a cup of coffee, half a lemon, and a glass of water. Estimations were made five times during the next three and a half hours. The basal metabolism rose to a maximum after one hour, when it was 20 per cent. higher than in the fasting state; subsequently it fell, till after three and a half hours it was only 4 per cent. above that of the fasting state. In a normal person the increase in metabolic rate caused by the ingestion of such a meal is between 20 and 40 per cent.; hence the figures recorded in this patient were definitely below normal. Three cases of ovarian insufficiency were studied; the decrease in basal metabolism was between 21 and 31 per cent. The author concludes that the estimation of the basal metabolism is of real value in the study of endocrine conditions; rendering it possible to follow the evolution of the disease, to assess the value of therapeutic measures, and in the case of hyperthyroidism to judge the gravity of the condition and the prospects of the patient.

#### 491. Changes in the Blood after Ultra-violet Radiation.

G. TOSI (*Raggi Ultravioletti*, July, 1926, p. 194) describes the effects of ultra-violet rays on the blood in a series of 28 cases. In the first group of 6 a Bach mercury vapour and a Sollux lamp were employed; in another group of 16 cases ultra-violet rays alone were used; and in a third group of 12 patients treated with ultra-violet rays alone the changes in the blood were noted at short intervals during a period of twenty-four to thirty hours. The third group showed leucocytosis immediately after irradiation, leucopenia half an hour to an hour later, and a second phase of leucocytosis six to twenty-four hours afterwards. Marked eosinophilia appeared immediately after irradiation, the number of eosinophiles being sometimes nearly doubled; lymphocytes, monocytes, and granular neutrophils were variously affected. These changes in the blood picture within a short period of time explain, according to Tosi, the conflicting results of different writers. After discussing various theories as to how the rays cause these changes, Tosi expresses his view that they are due to a specific reaction of the sympathetic following stimulation by the rays of the nerve terminations in the skin.

#### 492. Oatmeal Proteins.

GLADYS A. HARTWELL (*Biochem. Journ.*, vol. xx, No. 4, 1926, p. 751) agrees that proteins of vegetable origin are of lower biological value than those from animal sources, and that the small amount usually present contributes little to the protein ration of man. She finds that the amount of protein in oatmeal varies, according to different authors, from 11.9 to 16.1 per cent., and, taking even the lowest figure, this cereal appears to be a richer source of protein than vegetables and fruits; the earlier adverse opinions of American workers about the poor quality of oat protein has been modified of late years. By simple qualitative analysis she has obtained three proteins from oatmeal; two are soluble in cold water and the third is insoluble in water but soluble in strong alkali. Each protein gave positive sulphur and Millon's reactions, and the coagulable and insoluble protein in addition contained tryptophan. From this analysis it would be expected that oatmeal would provide a good source of protein in the diet. She describes experiments on rats, and concludes that the proteins of oatmeal are of good value as regards growth in rats. In gestation and lactation a diet of oatmeal, butter, and salt mixture was not found adequate, probably owing to deficiency in the quantity rather than the quality of the protein. The addition of food casein, gluten, gelatin, and egg albumen to the oatmeal diet produced better growth in the suckling young.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 493. Sympathetic Disturbance of the Heart.

A. DAMAS (*Journ. de Méd. de Lyon*, October 5th, 1926, p. 485) remarks that sympathetic disturbances may react on the heart either directly or through alterations of the pulmonary or general circulation. The clinical signs of such disturbances are arrhythmia, pseudo-angina, cardiac dilatation, and myocardial failure of the left ventricle, with such sequels as acute pulmonary oedema. Whether or no there has been in these cases an old cardiac lesion (as Vaguez believes), it would appear that these reflex disturbances do not occur under ordinary conditions. In the normal heart the effect of sympathetic disturbance is temporary, sudden, and prone to recur. The exciting cause of these cardiac manifestations may be pain in the liver or stomach or even in the peripheral nerves. Damas believes that such sudden sympathetic disturbances may also cause anaphylactic shock, notably digestive anaphylaxis in predisposed patients who are sensitized and perhaps suffer also from cardiac or aortic disease. Cardiac crises may be produced analogous to the "solar crises" of dyspepsia. Cardiac lesions, such as simple hypertrophy, coronary defects, and, still more, definite myocardial lesions, undoubtedly predispose to these attacks. Diffuse arterial lesions and interference with the mechanism regulating the blood pressure may assist in the production of these disturbances. The clinical difficulty consists in distinguishing between the nervous and organic factors. Purely sympathetic disturbances with sudden derangements in this part of the nervous system may produce cardiac inhibition and circulatory failure from pain or shock, but before admitting the functional reflex character of cardiac derangements the clinician must consider the predisposing cause, which may be a latent infection requiring prompt and judicious treatment.

### 494. Prophylaxis of Serum Disease.

H. HECKSCHER (*Acta Med. Scand.*, October 13th, 1926, pp. 497 and 505) maintains that a further study should be made before, during, and after the presence of serum disease, with special reference to the condition of the capillary system. He has observed 1,113 diphtheria patients treated by serum injections at the Högskolan Hospital. The serum was employed in two different concentrations, containing 400 and 800 units per c.c.m. respectively, the latter dose being used chiefly for intravenous injections; no artificial concentration was employed nor any kind of separation of the proteins, and chinosol was added as an antiseptic. The author agrees with earlier investigators that the volume of serum is an important factor in the occurrence of serum sickness, but, in contrast with earlier reports, finds that intravenous injections produce sickness in fewer cases than do intramuscular injections. Predisposition to serum disease increased considerably with age, was more marked in adults than in children, and was also more severe in children between 6 and 15 years of age than in younger children. With a view to giving prophylactic treatment during the period between the injection of serum and the development of the disease, which usually appears on the eighth day after the injection, Heckscher experimented with the injection of proteins. No peptone was used, but he employed a suspension of a polyvalent staphylococcus culture in physiological salt solution containing 1,000 million killed bacteria in 1 c.c.m. Increasing quantities were injected intramuscularly on five successive days, the fourth to the ninth day after the injection. The dose of vaccine for all patients under 15 years of age was 0.2, 0.5, 1, 2, and 3 c.c.m., and for all patients over that age 0.5, 1, 2, 3, and 5 c.c.m. Staphylococcus vaccine was employed as it was known to be an innocuous and effective form of non-specific protein therapy. According to the author this treatment has resulted in a reduction of the frequency of the serum disease, the percentage of cases having fallen by about one-third.

### 495. Epidemic Jaundice and Housing.

A. THISTED (*Ugeskrift for Læger*, September 9th, 1926, p. 223) notes that hitherto most of the publications dealing with the growing incidence of epidemic jaundice have come from countries involved in the late war. It might therefore be assumed that this growing incidence depended on circumstances connected with the war, such as underfeeding, which lowers resistance to infectious diseases, and chemical poisoning connected with the manufacture of explosives. But,

as he shows, though the Danes did not suffer from malnutrition during the war, the incidence of epidemic jaundice has greatly increased. According to statistics dealing with hospital returns in Copenhagen, there were in the period 1908-9 only 17 cases of catarrhal jaundice among a total of 5,358 hospital cases—an incidence of 0.32 per cent. In the period 1924-25 there were as many as 92 such cases among a total of 10,148 hospital cases—an incidence of 0.9 per cent. Again, between 1908 and 1916 there was not a single case of acute yellow atrophy of the liver treated in the hospitals of Copenhagen, whereas in the period 1922-23 there were as many as 6 such cases. The years in which the cases of catarrhal jaundice were most frequent were those in which there were several cases of acute yellow atrophy of the liver. Discussing the dependence of epidemic jaundice on infection and overcrowding, the author publishes a table showing the numbers of families unable to obtain housing accommodation from year to year in Copenhagen. According to this table there were only 14 such families in April, 1916. By April, 1919, this figure had risen to 1,274, and by April, 1925, to 2,113 families which could not find quarters because of the overcrowding and lack of housing accommodation in Copenhagen.

### 496. Glandular Fever.

C. W. BALDRIDGE, F. J. ROHNER, and G. H. HANSMANN (*Arch. Int. Med.*, October 15th, 1926, p. 413) record observations based upon a study of fifty cases of glandular fever (infectious mononucleosis), an acute infectious disease of unknown etiology, of short duration, and characterized by fever, enlarged glands, and the presence of abnormal mononuclear cells in the blood. The onset may be sudden, with high temperature and constitutional symptoms, but without localizing signs of infection, or the commencing signs may be sore throat and membranous angina, but with less fever and constitutional symptoms than in the previous type. In a third type the illness starts with some fever and tender glands, while in a fourth type the initial symptoms may be entirely abdominal, with pain, fever, and leucocytosis, the glandular signs appearing later. In some cases the onset and symptoms are so insidious as frequently to escape notice. Neither the organism causing the disease nor the portal of entry has been found, but the disease has occurred in well defined epidemic form, and the symptomatology is similar to that of other acute infectious diseases, with the addition of the enlarged tender glands. The great variability in modes of onset constitutes the chief difficulty in diagnosis. The total leucocyte counts are usually above normal at the onset but below normal during convalescence. A marked increase in abnormal mononuclear cells occurs during the course of the disease, the monocytes occasionally outnumbering the lymphoid cells. The occurrence of a relative or absolute lymphocytosis with abnormal lymphoid cells in the blood is significant only of acute lymphoid hyperplasia and is not specific for glandular fever, nor does the percentage of these abnormal cells bear any direct relation to the amount of glandular enlargement.

### 497. Protein Hypersensitiveness.

FROM observation of a series of cases H. C. STUART and MARINA FARNHAM (*Amer. Journ. Dis. Child.*, September, 1926, p. 341) advance the opinion that hypersensitiveness to food proteins tends to be present at birth and to be gradually lost during childhood, whereas hypersensitiveness to inhalant proteins tends to be acquired and is more resistant to change. The so-called natural loss of hypersensitiveness to food proteins may, they consider, be the result of frequent though unrecognized small doses of the offending substance in the diet, and may therefore correspond to desensitization treatment. The authors advocate active treatment by oral desensitization in these cases as preferable to awaiting the natural loss of such hypersensitivity. No child should be considered for long as sensitive to one or two particular proteins only, but as a complex of changing and multiple sensitizations. It is therefore imperative to retest at frequent intervals, preferably every six months, those who are not free from symptoms. There is evidence also that close contact with an inhalant protein in childhood increases the probability that the patient will become hypersensitive to that protein. It would therefore seem to be advisable to prohibit horseback riding and pets of all kinds, and forbid the use of feather pillows, hair mattresses, and fur coats by asthmatic children regardless of their response to tests for sensitivity to specific proteins.

## Surgery.

### 498. Arthroplasty of the Hip.

W. S. BAER (*Journ. Bone and Joint Surg.*, October, 1926, p. 769) records the results obtained in 100 cases of arthroplasty of the hip, in the performance of which he interposed an animal membrane taken from the pig's bladder and chloricized to last fifty days. A good result was obtained in 82 per cent. of the patients; there was free movement, and the joint was painless and stable in weight-bearing. The author finds that in gonorrhoeal arthritis the operation gives good results and assures the patient free mobility in the hip. In traumatic ankylosis also the results are, on the whole, very gratifying. In cases of septic infection of the hip the operation is said to be only applicable to certain cases after careful scrutiny. All signs of activity should have ceased for several years, and the patients should not be fat. The three deaths in the series occurred in this group. Baer states that in tuberculous infection the operation must be approached with caution. No child should be so treated, and only in cases where the general health is excellent should operation be undertaken. In well chosen cases good movable joints will follow. In arthritis deformans the operation should never be undertaken, since this is a chronic progressive disease which is still active and so negatives any operative procedure. It is generally agreed that little can be expected from an operation under these conditions.

### 499. Tetanus following Aseptic Operations.

A. KÖNIGSWIESER (*Münch. med. Woch.*, October 8th, 1926, p. 1703) records three fatal cases of tetanus which occurred after aseptic operations on the foot in the course of five years at Professor Spitz's Orthopaedic Hospital at Vienna in patients aged from 10 to 17. All the patients had been in the habit of going about barefoot in the neighbourhood of stables. The author suggests that after incision of the skin of the sole tetanus bacilli were carried into the deeper part of the wound. The method hitherto in use had been to give the patient a bath on the evening before the operation, and on the following morning to clean the operation area thoroughly with soap, disinfect it with tincture of iodine, and then apply a sterile dressing. Immediately before the operation the dressing was removed and the operation area disinfected again with alcohol and tincture of iodine. As the measures are not sufficient to disinfect the deeper layers of the skin it has become the practice in the Vienna Orthopaedic Hospital to give a prophylactic injection of tetanus antitoxin before every operation on the feet of the patients who have been in the habit of walking about barefoot.

### 500. Surgery of the Eustachian Tube.

T. H. HALSTEAD (*Arch. of Otolaryngol.*, September, 1926, p. 189) recalls the structure of the Eustachian tube. The pharyngeal portion has ciliated epithelium, a cartilaginous wall, and muscular tissue, all of which assist in protecting the deeper parts. The tympanic portion is rigid and devoid of muscular tissue; it is really part of the tympanic cavity. The position of the pharyngeal ostium makes the tube very liable to involvement in infections of the naso-pharyngeal region, with partial or complete closure. In this portion of the tube the disease is restricted to the mucosa and submucosa, but when it reaches the tympanic portion it is found that the mucosa is actually the muco-periosteum, and at an early stage granulation tissue and caries appear. Following a conservative mastoid operation the tube should be left as wide open as possible and granulations be gently curetted away. When there is a continued suppurative of the middle ear without mastoid involvement, in spite of all intratympanic treatment and attention to the nose and pharynx, then the tube should be closed. The radical mastoid operation should be completed by curetting the tympanic portion of the tube with curette and rasp. The closure is likely to be effected at the isthmus between the tympanic and pharyngeal portions of the tube. If any method of skin grafting be employed a portion of the graft should be applied to the wide open orifice of the tube. It may also be necessary to close the pharyngeal end of the tube by incising and drawing out the mucosal lining of the tube.

### 501. Spontaneous Gangrene of the External Genitals.

E. TEITSCHER (*Wien. klin. Woch.*, September 30th, 1926, p. 1177), who records a fatal case in a man aged 60, states that Fournier in 1883 described a special gangrenous affection of the male genitals, which appeared spontaneously, extended rapidly over the skin of the penis and scrotum, and frequently

destroyed the external genitals in twenty-four to forty-eight hours. Coenen and Przedborsky in 1911 collected 203 cases of gangrene of the external genitals in the male, 145 of which they regarded as spontaneous. According to Randall, the three principal symptoms of the disease are the sudden onset, the rapid progress and development, and the complete absence of the ordinary causes of gangrene. The disease usually attacks young healthy persons, the onset being accompanied by high fever, rigors, rapid pulse, vomiting, and often delirium. A slight redness and oedema appear and rapidly extend over the genitals, which become swollen to three or four times their normal size, and moist gangrene rapidly develops. Two groups of organisms have been found—namely, gas-forming bacteria and other pyogenic germs; especially streptococci. The disease is most frequent in war time, when many organisms acquire an increased virulence. Teitscher mentions that the first cases of the kind were described by Thucydides in the plague of Athens at the time of the Peloponnesian war. The mortality ranged from 20 to 23 per cent. Treatment consists in early and free incision and drainage. The use of Dakin's solution is also indicated, and a plastic operation may be required subsequently.

### 502.

#### Post-operative Parotitis.

I. SILBERMANN and M. KAGAN (*Zentralbl. f. Chir.*, October 9th, 1926, p. 2589) have seen twelve cases of post-operative parotitis among 3,665 surgical cases. Three cases occurred after operations on the uterus, one patient had had an operation on the vagina, five had had gastric or intestinal operations, and the other three patients had had herniotomy performed. Some authors suggest that post-operative parotitis is due to endocrine disturbance, others have found that 75 per cent. of the cases followed gynaecological operations, but the present authors have encountered this complication in only 25 per cent. of their operations of this nature. They observe that the post-operative period especially favours thrombosis and embolism, and they believe that the peculiar racemose structure of the parotid gland and its intimate relations with the external carotid and its branches make it particularly liable to the occurrence of embolism; the firm fibrous capsule and trabeculae of the gland, together with its close relation to the masseter muscle, aggravate the thrombosis that follows the lodging of emboli in the branches of the parotid arteries. The authors have examined sixteen parotid glands after death and have satisfied themselves that this explanation is correct. They conclude that the endocrine and stomatogenous theories of causation fail to explain the occurrence of post-operative parotitis, and that the majority of these cases are unconnected with the endocrine system and with operations on the genitalia.

## Ophthalmology.

### 503.

#### Carbon Monoxide Amblyopia.

W. R. MURRAY (*Minnesota Med.*, October, 1926, p. 561) thinks that chronic carbon monoxide poisoning may cause such common ailments as headache, dizziness, indigestion, palpitation, muscular weakness, psychic and even ocular disturbances, and is not to be overlooked in view of the extensive use of gas for heating, cooking, and illuminating purposes, the general use of coal stoves and furnaces, and the constant presence of carbon monoxide in the exhaust gases of motor cars. Where ventilation is efficient few ill effects are likely to result, but when this is not so, as, for instance, when people are working in almost hermetically sealed rooms, closed garages, or even in the vicinity of motor cars with the engine running, these symptoms are likely to be felt. He reports a case of amblyopia resulting from inhalation of carbon monoxide. A farmer, aged 24, complained of blurred vision one day after exposure for two hours to the exhaust fumes of a petrol motor; he had been similarly exposed on several previous occasions. A yellow spot appeared in the right eye and later changed to a dark blurred area in the field of vision. Two days afterwards the left eye was similarly affected. In both eyes the blurred spot appeared to have a revolving yellow halo around its periphery. The patient complained also of diplopia, nausea, vomiting, and headache. Two weeks later he had tenderness of the eyeballs on palpation, normal tension, injection of the bulbar conjunctivae, inequality of the pupils, reaction to light and convergence clear, intraocular media clear, blurred disc margins, slightly contracted retinal arteries, and relatively engorged veins. Visual fields showed contraction, with sector defects for red and blue; no scotoma was present and no enlargement of the blind spot. He was unable at this examination, or at any subsequent ones, to distinguish green

colour. Vision in the right eye was 20/200, and in the left eye 10/200. A general examination showed nothing abnormal, but the carbon monoxide haemoglobin test by caustic soda was positive. Two days later the spectroscopic test for carboxyhaemoglobin was negative, as also was the test by caustic soda. The bulbar and palpebral conjunctivae were slightly injected, the external ocular muscles were normal; there was no ptosis and no nystagmus. The right pupil was larger than the left, with sluggish reaction to light, and the intraocular media were clear; there was bilateral papilloedema, contraction of the retinal arteries, and dilated veins. A diffuse, gray-white opacity extended uniformly throughout retinal fundus and was but slightly elevated; there was a retinal oedema present. The vision was falling rapidly; he was able to distinguish moving objects, but was unable to recognize individuals. One week later his vision was reduced to the perception of hand movements before the eyes. Several weeks later there was retinal oedema, and large vitreous exudates were present; vision was reduced to perception of light. Fifteen months after the onset of the amblyopia ophthalmoscopic examination showed extensive choro-retinal lesion, without pigment, scattered throughout the fundus, and opacities in the vitreous. The vision in the right eye equalled 10/200 and left eye 2/200. Murray explains the ocular nerve lesions as being due to involvement of the nuclei of origin of these nerves. The fibres of the optic nerve apparently are not especially susceptible to the poison, neither are the papillomacular fibres.

#### 504. The Action of Atropine in Ocular Inflammations.

T. H. ADLER (*Arch. of Ophthalmol.*, September, 1926, p. 484) suggests that the benefit of atropine in inflammations of the eye may be due to something more than the anatomical and physiological rest produced by the paralysis of the ciliary and iris sphincter muscles. He states that atropine has a direct action on the blood vessels of the eye, decreasing their permeability to protein. It was found experimentally that when the eye was inflamed by the instillation of ethyl-morphine hydrochloride the protein content of the aqueous was increased, but if the eye had first been treated with atropine this increase of protein in the aqueous did not occur. Adler suggests that this action of atropine may account in part for its beneficial effects in ocular inflammations.

#### 505. The Trapezoidal Flap in Cataract Operations.

J. GREEN (*Journ. Amer. Med. Assoc.*, August 7th, 1926, p. 392) describes his method of safeguarding cataract expression. He advocates a preliminary iridectomy under a trapezoidal conjunctival flap; this heals rapidly without reaction, the chances of infection are reduced to a minimum, and provision is made for artificial maturation in cases of cataracts found to be immature. With this technique any unwillingness of the patient does not imperil the success of the iridectomy, and the operator will have been warned in time to take special precautions during the expression four to six weeks later. The trapezoidal flap has similar advantages to the small triangular flap, and, moreover, the flap is thicker and sturdier; it covers the entire section, and is held in good position by the central Verhoef stitch and the lateral conjunctival sutures. With the Verhoef suture loosely tied the flap is drawn into good position and irrigation of the chamber can be performed with great security; should the vitreous present or prolapse the immediate tightening of the suture will deal with it. There is little tendency for prolapse of the iris, and any iritis is easily controllable by atropine, heat, and salicylates. Anterior synechiae are rare, and there are a large number of "keyhole" pupils. The secondary membrane is usually very thin and can be sufficiently slit by a single vertical incision. Thick membranes are dealt with by Ziegler's inverted V-shaped dissection.

#### 506. Ocular Complications in Raynaud's Disease.

S. J. APPELBAUM and M. L. LERNER (*Amer. Journ. Ophthalmol.*, August, 1926, p. 569) describe a case of Raynaud's disease in which ocular complications developed. In a married Jewess, aged 45, dry gangrene appeared in the distal phalanx of the left index finger. She had temporary loss of memory, numbness, and pricking sensations in the fingers and feet, and attacks of "migraine." At the height of the attack bilateral papilloedema, associated with haemorrhage and exudates, occurred. This condition finally cleared up, leaving an apparently healthy fundus, but with very contracted retinal arteries. The resulting vision was 6/9 in each eye. During the illness there was much pain in the eye, but the vision was never seriously affected, even when the papilloedema was most marked.

## Therapeutics.

#### 507. Paravertebral Injections of Alcohol in Angina Pectoris.

F. BRUNN (*Wien. klin. Woch.*, September 23rd, 1926, p. 1110) has applied the principle of paravertebral blocking of the rami communicantes in the upper dorsal segment to the treatment of angina pectoris. His first patient, a man aged 67, suffered from aortic regurgitation with severe dyspnoea, and radiating pains in the cardiac region and right arm. A bilateral resection of the depressor nerves, performed six months earlier, had lost its effect a month afterwards. This patient was relieved for eleven days by a paravertebral injection of novocain. After a paravertebral injection of alcohol he lost the precordial pain and suffered only from simple cardiac asthma. Brunn refers to the earlier use of cocaine injections in the treatment of angina pectoris; a single injection into the trunk of the cervical sympathetic relieved severe thoracic and brachial pain in a case of aortic regurgitation in a man aged 70. These successes suggested the possibility of blocking the rami communicantes in the upper dorsal segment. Subsequent experience has proved the value of this treatment in angina pectoris and aortalgia. Brunn refers to the good results obtained in America by Swetlow and Schwartz from the injection of 85 per cent. alcohol, though a 60 per cent. solution of alcohol was less efficacious. Their five cases included three of angina pectoris, one of aortic regurgitation of coarctation of the aorta, and one of decompensated mitral disease. The authors found a hyperaesthetic and hyperalgesic zone in the upper dorsal region, which indicated the region to be anaesthetized; these areas became, after injection, persistently analgesic to pain and high temperature. The patient who suffered from mitral regurgitation lived for fourteen weeks after the injection of alcohol and was free from pain. In one case of angina pectoris pulmonary oedema occurred after the injection of alcohol.

#### 508. Dietetic Treatment of Renal Impairment.

P. LOMAY, L. GILLET, and L. DUBLE (*Bruxelles Méd.*, September 26th, 1926, p. 1443) have followed up over 100 cases of renal insufficiency correlating the clinical findings and laboratory reports. They find that excessive intake of fluid is a common cause of renal insufficiency, and instead of "washing out the kidney," it over-fatigues it. The daily fluid allowance should be 1½ litres; more than this may cause rise of blood pressure, without arterio-sclerosis, and in the absence of abnormal constituents in the urine and of excess of blood urea or chlorides. In support of this they describe two cases out of many observed; in both cerebral haemorrhage was threatened, and the only cause was the excessive consumption of fluid, amounting to about three quarts daily. Uræmia may or may not be associated with hypertension, albuminuria, salt retention, or arterio-sclerosis; the clinical symptoms are practically those of simple hypertension, and the two conditions are distinguished by urinalysis, uræmia being always accompanied by tube casts. The authors add that the onset of uræmia and arterio-sclerosis is best avoided by a small protein intake; salt retention by a reduced use of salt in cooking, and the addition at table of not more than 2 to 3 drachms a day. From the age of 40 onwards the blood pressure should be watched and the urine analysed; should a rise of pressure be found without tube casts in the urine, there is no need for blood analysis. The diet should be very carefully arranged as to quantity, both of liquids and solids.

#### 509. Medicinal Treatment of Duodenal Ulcer.

DISCUSSING the treatment of early duodenal ulcer, H. C. MOFFITT (*Canadian Med. Assoc. Journ.*, September, 1926, p. 1044) warns against the excessive administration of alkalis, especially in cases of gastric retention or in coincident renal or hepatic disease. He suggests certain modifications in the Sippy treatment, including the substitution of neutral calcium or magnesium phosphate for the magnesium, sodium, or calcium compounds recommended by Sippy. Intervals between feedings may, in a few days, be increased to two hours in many cases, and a soft diet started in the second week. Moffitt finds that some patients do better on carbohydrates and eggs from the start than on a milk diet, and that the large doses of alkalis recommended by Sippy are not necessary in most cases. Tincture of belladonna is suggested as a valuable addition to the alkali treatment, while bromides or luminal are often useful to control general nervousness and to lessen reflex irritation. The author thinks that protein shock treatment is probably without value, but that x-ray treatment should be given a more thorough trial. Lavage, transfusion, control of alkali dosage, glucose by

rectum or intravenously, and the hypodermoclysis of 1 per cent. saline solution are recommended as measures which have contributed greatly to favourable operation results. Moffitt adds that post-operative treatment should include confinement to bed for three or four weeks, strict supervision for six to eight weeks, and a modified Sippy treatment with smaller doses of alkalis and less frequent feedings throughout this period. The subsequent life should be carefully regulated, and alkalis and belladonna be given if the symptoms recur.

## Obstetrics and Gynaecology.

### 510. Uncontrollable Vomiting of Pregnancy.

In a case of uncontrollable vomiting of pregnancy reported by GUYOT, J. PÉRY, and MAILHE (*Bull. Soc. d'Obstét. et de Gynecol. de Paris*, July, 1926, p. 450) there had been three previous abortions, vomiting being absent in the last two. After admission to hospital the patient had two attacks of petit mal, the crises lasting from five to ten minutes. The Wassermann reaction was negative, and nothing abnormal was found in the urine. As the vomiting, which commenced with the pregnancy, resisted other forms of treatment, enemata of milk containing 3 grams of chloral hydrate were administered three daily at intervals of six hours. For five days the vomiting continued, but gradually lessened, and at times consisted only of bile. After three weeks it ceased, the daily amount of chloral being reduced from 9 to 6 grams. The general state of the patient improved, and the pregnancy proceeded normally to full term. This method of treatment has been advocated also by d'Anvers.

### 511. Diathermy in Pelvic Inflammation.

R. L. IMPEY (*South African Medical Record*, September 25th 1926, p. 393), after a year's trial of diathermy in the treatment of inflammatory conditions of the female pelvis, with special reference to gonorrhoea, believes that when used in conjunction with local applications it reduces considerably the time taken in curing the condition, and is probably more effective than other measures. Diathermy raises the temperature of the subjected part, and this rise of temperature, be it only a few degrees, is prejudicial to the existence of the gonococcus, while it is followed by a local polymorphonuclear leucocytosis which increases the power of the tissues to exterminate the organisms. The technique adopted by Impey is similar to that recommended by Cumberbatch and Robinson. Both urethra and cervix are treated, and since the cervix is not sensitive to heat the thermometer must be watched lest the temperature exceed 115° F. Following each diathermy treatment local applications, such as silver nitrate, mercurochrome, picric acid, and 10 per cent. solution of protargol in glycerin, are made in order to attack the gonococcus at a time when its vitality is low. Such combined treatment is repeated two or three times a week until all clinical and bacteriological evidence of disease is absent. He cites two cases disproving the belief that when once infected a woman never gets rid of gonococcal infection, and he holds that when thoroughly treated with local applications as well as by diathermy she should recover completely without any after-effects.

### 512. Low Caesarean Section.

LE LORIER (*La Gynécologie*, July, 1926, p. 425) during the performance of low Caesarean section on seventeen occasions has not had one maternal death, and only one infant succumbed, this being prior to the start of the operation. Low Caesarean section was performed in twelve cases of pelvic deformity; in one case for placenta praevia with pelvic stricture, and in another case for simple placenta praevia; in two cases for prolapse of the cord with rupture of the membranes, and in one for ovarian cyst. One patient had previously undergone three hysterotomies, and two other patients had been twice operated upon in this way. One death occurred four hours after operation from haemorrhage due to uterine inertia, and in two other patients serious haemorrhages were controlled. In eleven cases there was pyrexia during the post-partum period. Le Lorier gives an injection of 1 c.cm. of ergotine immediately before the commencement of anaesthesia; on one occasion pituitrin was used. The uterus is sutured in one plane with catgut. The author claims that the advantages of low Caesarean section are: the easy performance of any additional measures that may become necessary, better protection for the peritoneum, and greater security of the uterine sutures made in non-contraction tissue. The disadvantages are: the danger of rapid and profuse haemorrhage, lessened facility for the extraction of the foetus, and the risk of leaving a tumour near to and behind the ovary.

## Pathology.

### 513. The Nature of Malignant Lymphogranuloma.

F. P. WEBER (*Strasbourg Méd.*, July 5th, 1926, p. 255) states that the majority of authors consider malignant lymphogranuloma as an infection of unknown origin attacking the lymphatic system first and commencing most often in the cervical or axillary ganglia. As the affection progresses and the infective agent multiplies, the whole of the lymphatic system is invaded and nodules appear in other organs, particularly in the liver. The lymphogranulomatous processes are able to pass through the capsules of the lymphatic ganglia and provoke a periglandular infiltration with sclerosis. In the liver necrotic areas often appear, capable of extending to neighbouring tissues. In rare cases there is a certain degree of amyloid degeneration in the spleen, kidneys, and other accessory organs. In cases of long standing the process is often associated with an intense chronic sclerosis which predominates at certain points, while at others the lymphogranulomatous process is plainly active. When the lymphadenoid tissues have been reduced by necrosis or sclerosis, the lymphocytes tend to diminish in number, although there is sometimes an excess of compensative or regenerative hyperplasia of the lymphadenoid tissue. Weber asks if the malady may sometimes assume a true sarcomatous aspect. In other words, can a sarcoma of Hodgkin develop from a granuloma of Hodgkin? Ewing believes that it can do so. The structure of the sarcoma presents an appearance ranging from a simple granuloma of Hodgkin to that of a tissue composed solely of large round cells. Large round giant cells, either polynuclear or multilobed, may predominate. The proportion of lymphocytes may be considerable, but not in the course of more obviously neoplastic processes. The histological signs of malignancy are not very marked, and it is very difficult to determine at what moment the lesions commence to become malignant. However, Ewing states that the metastatic nodules in the dura mater and lung, and also the cytological changes, prove the malignancy of the tumour. Weber describes in some detail a case of his own, and believes that in rare cases the lymphogranulomata of Hodgkin may become sarcomatous or may provoke such malignancy by chronic irritation. He suggests as being analogous the idiopathic multiple haemorrhagic sarcoma of Kaposi, which occurs among the Jews of Central Europe. This affection is considered as being inflammatory, but of unknown cause, and not sarcomatous or malignant. However, Weber adds, a true sarcoma has developed on this inflammatory condition in one or two of these cases, or some part of the inflammatory tumour has undergone sarcomatous transformation.

### 514. The Reticulo-endothelial System and Anaemia.

A. R. ELVIDGE (*Journ. Path. and Bact.*, October, 1926, p. 325) records the experimental production of blood crises and of anaemia in rabbits as the result of injections of finely divided particles of foreign matter. The first observations were made with suspensions of quartz; the size of the particles varied in different experiments, but they were usually about 1 to 7  $\mu$  in diameter. The fluid in which they were suspended was made isotonic with the blood plasma by the addition of dextrose, and was injected intravenously in a dose varying from about 5 to 50 c.cm. A single injection caused the appearance of nucleated red cells in the circulation. These were first observed about five hours later; they increased to a maximum in twenty-four to forty-eight hours, and then gradually diminished, till after a fortnight they had completely disappeared. The majority of these cells were normoblasts, but at the height of the blood crisis macroblasts, and occasionally megaloblasts, were present. Though a single injection did not produce any alteration in the number of red cells, repeated injections led to a marked diminution, sufficient sometimes to prove fatal. In one experiment the red cells sank after three injections from about seven million to about one million per cubic millimetre. The haemoglobin decreased *pari passu*, so that the colour index remained at unity. It was thought that the anaemia might be due to a poisoning effect of the silica, but this was not borne out by experiments designed to test it. Very finely divided particles of quartz—less than 1  $\mu$  in diameter—and silicic acid gel failed to reproduce the anaemia, suggesting that this condition was due not to the chemical effect of the silica but to the physical properties of the particles. Confirmation of this was afforded by the reproduction of anaemia with particles of other substances—Indian ink and carmine. The author considers that the particles of suspended matter, provided that they are not too fine, act by blocking the cells of the reticulo-endothelial system and interfering thus with the normal generation of the red cells.

# EPITOME OF CURRENT MEDICAL LITERATURE.

THE BRITISH MEDICAL JOURNAL 87

## Medicine.

### 515. Differential Diagnosis of Cerebral Syphilis.

J. J. MINOGUE (*Med. Journ. of Australia*, October 2nd, 1926, p. 444) divides cerebral syphilis into two groups—the meningo-vascular and central syphilis, which includes general paralysis of the insane and tabes dorsalis. In the meningo-vascular form three processes are at work: slowly advancing meningitis, gummatous formation, and lucid rascular diseases. If cerebral gummatous formation, and lucid rascular diseases, are present a clinical problem arises. Specific meningitis manifests itself usually in the form of cranial nerve paralysis, usually of the third nerve, and the diagnosis is simple. Specific vascular disease may be diffuse or limited in extent; the brain substance is affected, not only by the damaged circulation, but also by the syphilitic toxin; the bewildering array of nervous and mental symptoms includes all forms of paralysis, epileptic form seizures, aphasia, sensory disturbances, apoplexies, and mental deteriorations of varying degrees. In the more severe grades this mental deterioration approaches very closely to that of general paralysis of the insane, a condition known as the pseudo-paralysis of the insane, a condition in which no anatomical basis can be demonstrated: these lesions Krappe described numerous other specific syphilis states, and acute hallucinatory psychosis. Minogue states that a differential diagnosis of all these lesions is impossible, but that in every nervous lesion of syphilis must be considered as a possible cause and evidence of it sought by a Wassermann test of the blood, and, if necessary, by a full examination of the cerebro-spinal fluid. The presence of an Argyll Robertson pupil is almost pathognomonic of cerebral syphilis, though its absence is fairly common. In the differential diagnosis of general paralysis of the insane it must be remembered that the ultimate result of this disease is a widespread degeneration of the cerebral cortex, and therefore only the three diseases giving rise to a similar degeneration need be considered—namely, alcoholic pseudo-paralysis. The diagnosis of general paralysis of the insane rests upon the history and a full physical and mental examination. This disease occurs in the prime of life and the typical clinical signs are the general bearing of the lips and tongue, slurring of speech, and a mild marked cortical degeneration. After prolonged illness and the diagnosis rests upon the history, visual hallucinations which are rare in general paralysis, and negative findings in the blood and cerebro-spinal tests. In arterio-sclerotic insanity the disintegration of the personality is rarely so profound as in general paralysis, and the disease occurs much later in life, there are signs of advanced arterio-sclerosis, and the blood and cerebro-spinal fluid give normal findings. The diagnosis of the pseudo-paralysis of Krappe is very difficult, and in the majority of cases rests upon the examination of the cerebro-spinal fluid. There is often the only criterion; the general paralytic will live as a hopeless dement for years, while the pseudo-paralytic will live as a hopeless dement for a few months of the disease is of the cerebro-spinal fluid, and ultimately rests on a Wassermann test of the blood and a full examination of the cerebro-spinal fluid. The latter should include a Wassermann test, a cell count (for lymphocytosis), and the globulin colloidal gold tests. Normal findings will at once exclude alcoholic and arterio-sclerotic insanity, and positive ones will certainly indicate the presence of syphilis. Fluids from general paralytics are much more responsive to these tests than those from patients with meningo-vascular syphilis, while the colloidal gold test would give the typical parietic curve (5555432000). In cases of doubt, the re-examination of the cerebro-spinal fluid after a few months of energetic treatment will usually decide whether the disease is of the parenchymatous or interstitial form.

### Ventricular Extra-systoles.

L. GALLAVARDIN (*Journ. de Méd. de Lyon*, September 20th, 1926, p. 449) draws attention to the danger of administering digitalis in certain forms of heart disease. In serious cases of valvular or myocardial origin, a special syndrome exists, with periodical arrhythmia and the possibility of sudden death. Digitalis may accelerate the onset of this syndrome, although it does not actually produce it, the origin being in the defective myocardium. Electrocardiograms show that

ventricular extra-systoles are always present (terminating frequently in complete arrhythmia) with complex electrical alterations; these are often polymorphic and tend to give place to series of extra-systoles, or even to more or less prolonged periods of ventricular tachycardia, leading to ventricular flutter. Ventricular fibrillation ends the series, which explains the occurrence of sudden death when these disturbances of rhythm exhaust the myocardium. Extra-systoles may occur without organic disease, causing much distress in well compensated valvular disease, causing much distress for a time, but finally disappearing without leaving behind any serious symptoms or signs. Extra-systoles occurring about the fiftieth year of life indicate a latent hypertension which is about to cause trouble—such as cardiac dilatation. Since 1850, periodical arrhythmias due to digitalis have been recorded in mitral disease with advanced dilatation and in myocardial sclerosis with advanced dilatation and administration of digitalis to healthy subjects does not produce such arrhythmia, but in serious cases of heart disease it is produced or aggravated by this drug. This occurs usually in the last few months of life; it may appear quite suddenly after the administration of an ordinary dose of digitalis, in a patient who has been under treatment for a long period, without any irregularity having been observed. Ouabaine, like digitaline, may provoke or increase a bigeminal pulse. Sudden death is most frequently observed in cases of cardiac hypertrophy showing arrhythmia due to digitalis. One patient died nine days after receiving 1 mg. of digitaline, and a second patient died twelve hours after, although the conditions seemed favourable and the bigeminal pulse had disappeared for several days. The author reports a number of similar cases in his own practice, although death did not occur so suddenly.

### Artificial Pneumothorax.

517. ACCORDING to J. F. FREIXAS (*Presse Méd.*, October 6th, 1926, p. 1253) the three indications for artificial pneumothorax are: to diminish and even abolish the transmission of pulmonary sounds from the affected to the healthy side; to treat profuse or persistent haemoptyses; and to cause collapse of the lung in pulmonary tuberculosis. The operation, though simple, may generate pleural reflexes, changing a favourable into a bad prognosis, and it may produce large haemorrhagic infarcts at the base of the free lung, and also gas embolism. Freixas suggests the following procedure to obviate these dangers. A simple blunt platinum needle, 7 cm. long and 1 mm. in diameter, is inserted in the eighth intercostal space at the common point of the costo-vertebral groove external to the sharp curvature of the costal arch, and pushed firmly and obliquely in a direction parallel to and contiguous with the ninth rib. After verifying the immobility of the needle, and observing by a manometer the characteristic oscillations caused by the respiratory movements, the insufflation of oxygen is commenced, attention continuing to be paid to the manometric oscillations. The author asserts that with this method he has had no untoward results, and that it has the double advantage over other methods of not provoking complications by the passage of the needle across the intercostal space, and also of offering the greatest chances of success from the point of view of introducing the needle between the two pleural layers.

### Abdominal Pain after Pleurisy.

518. S. PLASCHKE and K. WEISS (*Wien. Klin. Woch.*, October 14th, 1926, p. 1210) report that vague gastric symptoms may have their origin in a previous adhesive pleurisy, usually of a basal or diaphragmatic type. They quote cases in their own experience and cite the literature on the subject. The symptoms are, as a rule, similar to those of a gastric ulcer, but x-rays show an elevation of the fundus due to the previous perigastritis; the stomach also is usually enlarged. The authors believe that this type of case, which is more often than not of tuberculous origin, is commonly than is generally realized.

### Atypical Cerebro-spinal Fever.

519. A. M. LITVAK (*Arch. of Pediat.*, September, 1926, p. 620) records a case of cerebro-spinal fever in a boy, aged 6 years, in whom catarrhal symptoms predominated for six days, before the onset of the meningococcal syndrome. Culture of the larynx showed that the catarrh was caused by invasion by the meningococcus. The laryngitis was so marked that intubation was necessary—a very rare occurrence in cerebro-spinal fever. The boy died on the ninth day of the disease, and the necropsy revealed catarrhal laryngitis and purulent meningitis.

## Surgery.

### 520. Squamous-celled Carcinoma in the Neck.

ACCORDING to R. V. HUDSON (*Brit. Journ. Surg.*, October, 1926, p. 280) patients are occasionally seen with a tumour in the neck resembling squamous carcinoma. In such cases the diagnosis rests between a primary carcinoma of branchiogenic origin or a carcinoma secondary to a healed or undiscovered focus somewhere in the body. Six cases of this nature are recorded; all the patients had been subjected to chronic irritation of the upper respiratory tract as a result of working in mines and with horses. In only one case was a necropsy possible, and in this the primary focus was found in the pyriform fossa; in others it appeared probable that the tumours had originated from a primary focus in the region drained by the jugulo-digestic gland. Hudson considers the surgical treatment of this condition to be invariably disappointing, owing to the difficulty of early diagnosis and the presence of the primary focus acting as a neoplastic cell depot; radium is the method of choice. The diagnosis depends principally upon the anatomical site of the tumour and its consistency. The swelling most likely to cause difficulty is the true branchiogenic carcinoma arising in a pre-existing cyst. This tumour, however, originates lower in the neck and is cystic in parts. The presence of a unilateral painless swelling in the neck of elderly men should arouse suspicion of malignancy.

### 521. Treatment of Liver Abscess.

H. COSTANTINI (*Rev. de Chir.*, No. 6, 1926, p. 357), discussing the treatment of liver abscess, states that although the introduction of emetine has profoundly modified the views held previously, there are certain cases where surgical treatment is necessary. Operation is indicated when there is a large collection of pus which is affecting the patient's general health, also where a secondary infection is present, and where, despite emetine treatment, the pyrexia continues. Costantini advocates the treatment of liver abscess by evacuation and suture without drainage under certain conditions and where no other infection is present. The abscess is incised where best access can be obtained. If the collection is posterior, the most common situation, the tenth rib is resected and the abscess reached through the pleural cavity. If the abscess is near the gall bladder or in the left lobe the abdominal route is chosen. In ten cases treated by suture after evacuation of the pus nine were cured and one died. The author adds that, whenever possible, exploratory puncture should be avoided, as it is often unnecessary and dangerous. The clinical signs should give material for a correct diagnosis. The method described of treating this condition enables the abscess to be completely evacuated, and by closing the wound afterwards it affords the maximum of safety.

### 522. Diagnostic Errors in Severe Gastric or Intestinal Haemorrhage.

J. PETERMANN (*Zentralbl. f. Chir.*, October 9th, 1926, p. 2591), has seen, during the last two years, no fewer than six patients who exhibited such severe and persistent gastric or intestinal haemorrhage that he has abandoned the expectant form of treatment in favour of immediate operation in all cases in which the patient's life is endangered. As examples of diagnostic difficulty he cites the following cases. (1) A powerful man, aged 46, had suffered for three years from pain attributed to duodenal ulcer; in the last few months he had had several considerable attacks of melaena. Both the skiagram and the analysis of the stomach contents indicated gastric ulcer. At the operation no sign of disease, either of the stomach or duodenum, could be found. The possibility of hepatic cirrhosis induced Petermann to perform Talma's operation, but subsequent blood examination revealed thrombopenia, so that splenectomy and irradiation would have been the correct treatment. (2) A man, aged 56, had complained for a year of pains in the stomach; he had undergone several "cures" for gastric ulcer. For two months he had severe attacks of haematemesis almost daily. He was very debilitated and collapsed when sent to hospital for operation for gastric ulcer, but a fatal attack of haematemesis occurred. The necropsy revealed hepatic cirrhosis. (3) A man, aged 23, had been under treatment for gastric ulcer for eighteen months; during the last month he had had numerous attacks of haematemesis, the last persisting for three weeks. The only abnormality found at operation was a group of enlarged glands at the lesser curvature; there was no sign of gastric or duodenal ulcer. The patient died two months later with hepatic cirrhosis. (4) A woman, aged 35, suffered for several months from sudden attacks of epigastric pain attributed to cholecystitis (cholelithiasis) or gastric or duodenal ulcer. Shortly after the stomach had been skigraphed a severe haematemesis occurred, and the

patient died before an exploratory operation could be performed. The necropsy proved that it was a case of myelogenous leukaemia. There was no evidence of gastric or duodenal ulcer. (5) A man, aged 40, had suffered for three years from sudden attacks of epigastric pain. Two years previously he had had cholecystectomy performed for contraction of the gall bladder. The epigastric pain did not diminish and serious fainting fits, with frequent attacks of melaena, occurred, suggesting the presence of ulcer or carcinoma. The patient was in an exhausted state, and melaena persisted. At an operation periduodenitis and perigastritis were found, and, on the assumption that an ulcer was present, a resection of the antrum and first part of the duodenum was undertaken. The patient collapsed and died fourteen hours later. The adhesions around the stomach and duodenum were the result of the previous cholecystectomy; no ulcer was found. The necropsy proved that the cause of death was pernicious anaemia. Petermann adds that these cases show that before an operation for gastric or intestinal haemorrhage is undertaken a thorough clinical investigation should be made and the blood should be carefully examined.

## Therapeutics.

### 523. Ultra-violet Rays in Therapeutics.

A. C. ROXBURGH (*St. Bartholomew's Hosp. Journ.*, November, 1926, p. 19) gives an account of the results obtained by the use of ultra-violet rays in a variety of conditions during a period of about twenty-one months. The types of lamp used were the large 75-ampere, short-flame, with open carbon arcs, and the air-cooled mercury vapour lamp. Of 272 patients suffering from fifty-six different diseases, 20.8 per cent. were very much improved, and 46.5 per cent. were improved. In eight cases of rheumatoid arthritis the appearance of the joints was but little altered, but the pain was diminished, movement became freer, and the patients' general health was improved. Tuberculous glands responded well, though not infrequently caseation occurred before healing commenced. In three cases of tuberculous joints the results were disappointing, though one patient gained several pounds in weight during the treatment. In lupus vulgaris the results, though useful, did not approach the over 50 per cent. of cures reported by some clinics as the result of combined treatment with Finsen light and general light baths. The author thinks it is evident that most cases of lupus vulgaris require both local and general treatment. Tuberculous peritonitis responded badly to treatment, and in acne vulgaris the results were less striking than after treatment by x rays. Non-tuberculous ulcers did well, and in the case of one child with extensive ulceration of the legs of undetermined origin, ultra-violet rays induced a rapid cure, after x rays, scraping, novarsenobillon, and other agents had failed. Benefit was noticeable in cases of extensive psoriasis, chronic alopecia areata the results were less satisfactory, of 23 being either cured or much improved, and 7 being unaffected. Roxburgh agrees that in many cases the benefit derived from ultra-violet rays is due to improvement in the general health and resistance.

### 524. Treatment of Encephalitis.

HEINICKE (*Munch. med. Woch.*, October 1st, 1926, p. 1647) thinks that in the acute form of encephalitis serum from a convalescent is the only means of treatment which appreciably reduces the death rate or minimizes the after-effects. In the pseudo-neurasthenic stage it is also of use. In addition to serum, colloidal silver, trypanflavin, and especially sodium salicylate, may be tried. Heinicke insists that treatment may prove effective even in chronic cases. The prognosis is, he thinks, best in the type of case with psychic disturbance, especially in children and young people; but these call for treatment lasting for many years. Such treatment is for the specialist and the educationist; it can, as a rule, only be made available in institutions where nervous symptoms can be treated and where, at the same time, opportunities for education on suitably and steadily graded lines are available.

### 525. Turpentine Treatment of Epididymitis.

J. O. RUSH (*Urol. and Cutan. Rev.*, October, 1926, p. 581) records observations on 50 cases of epididymitis, 47 of which were gonorrhoeal and 3 traumatic, treated by injection of turpentine beneath the periosteum of the ilium, as recommended by Wren and Tenebaum in 1924. A 20 per cent. emulsion of rectified turpentine oil in sterile olive oil was used in doses of from 0.5 to 1.0 c.cm. at a time, the injections being repeated every other day. No other treatment was employed. Examination of the urine showed that no renal lesions followed. In some cases the pain in the testicle began to subside in from one to three hours after the first

injection. In febrile cases there was a sudden drop of the temperature, which reached normal in thirty-six hours, in marked contrast with the rise of temperature following protein injection. Rush concludes that this method is superior to any previous one for the treatment of epididymitis. The duration of treatment was markedly reduced, the pain was quickly relieved without the use of narcotics, sedatives, or analgesics, and the use of ointments, caustics, and other methods was rendered unnecessary.

#### 526. The Vaso-dilator Action of Benzyl Benzoate and Acetate.

D. SIMICI and I. MARCU (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, October, 1926, p. 654) refer to the hypothesis that the sedative and paralyzing action of papaverine is actually due to its benzyl radical. Animal experiments have shown that benzyl benzoate has sedative properties similar to those of papaverine; it has a powerful antispasmodic action on unstriated muscle. It has been employed as a hypotensor in transient or permanent arterial hypertension, in angina pectoris, and in intermittent claudication. It has also been useful in muco-membranous enterocolitis, spastic constipation, and dysmenorrhoea. The authors have made numerous plethysmographic tracings and simultaneous sphygmomanometric observations in order to determine the pharmacodynamic action of both drugs on the vascular muscle fibres. They found that both benzyl benzoate and benzyl acetate were inert when administered orally, even in such large doses as 120 minims of a 25 per cent. solution of the benzoate; but when 30 minims of a 20 per cent. oily solution of this substance were injected intramuscularly a pronounced vaso-dilatation occurred in six minutes and persisted for forty minutes. In this case the arterial pressure remained unchanged, showing that the vaso-dilatation was purely a peripheral phenomenon, due to the direct action of the drug upon the unstriated muscular fibres of the arterial wall. A second tracing showed that after the injection of 75 minims of the same solution a very definite vaso-dilatation occurred in eight minutes, and lasted for ten minutes, after which it returned slowly to the normal. During this period the maximum and minimum blood pressures fell slightly owing to a moderate central vaso-dilatation; this disappeared on the return of the tracing to the original level. The authors conclude that alcoholic solutions of benzyl benzoate, when administered in large doses by the mouth, are practically inert; but that the drug is a powerful vaso-dilator when injected in oily solutions. Benzyl benzoate and acetate very frequently exhibit a hypotensive action on the central as well as on the peripheral vessels. The vaso-dilator and hypotensive phenomena occur in normal subjects and also in patients suffering from hypertension without arterio-sclerosis. These drugs appear to be inert in arterio-sclerosis.

## Dermatology.

#### 527. Erythema Multiforme and Erythema Nodosum.

G. BLUMER (*Boston Med. and Surg. Journ.*, September 9th, 1926, p. 515) calls attention to the febrile types of erythema multiforme and erythema nodosum and discusses their relations and the possibility that the two conditions are of similar etiology. In the febrile type of erythema multiforme there is a prodromal period with fever, and in some cases joint pains and general aching, followed by the appearance of the rash and a period of convalescence. The evidence of the occurrence of erythema nodosum as a specific disease is much more convincing than that concerning erythema multiforme, and it is the occasional occurrence of several cases in the same family and of small groups of cases in institutions and of considerable numbers in certain districts during limited periods of time that points to the existence of a definite febrile type of erythema nodosum. From his observations and from those recorded by others Blumer considers that febrile types of both conditions may exist which are not obviously secondary to preceding infections or intoxications, and that there is some evidence of an epidemiological nature, which suggests that febrile erythema multiforme and febrile erythema nodosum may be specific infectious diseases and manifestations of streptococcus infection. Although it cannot be proved, in the absence of the discovery of the etiological agent or agents, it is possible that they are both expressions of the same form of infection.

#### 528. Generalized Telangiectasia.

S. W. BECKER (*Arch. Derm. and Syph.*, October, 1926, p. 387) contributes a clinical study of generalized telangiectasia, with special consideration of its etiology and pathology; he recognizes three groups—generalized telangiectasia, non-hereditary and non-familial telangiectasia with involvement

of the mucous membranes, and livedo racemosa. Appearing in the majority of cases during the second decade, females are affected more than twice as frequently as males. The etiological classification into neurogenous, mechanical, and toxic accounts for all cases. Of seven cases specially studied Becker considered one to be an example of livedo racemosa, one of non-hereditary involvement of the mucous membranes with haemorrhage, two due to prolonged infection, two of neurogenic origin, and one of combined endocrine disturbance, infection, cardio-vascular involvement, and a tendency toward neoplasia. In most cases there appears to be a multiplicity of conditions, and the frequency with which exposed surfaces are involved points to trauma as an etiological factor. The prognosis is favourable except where there is involvement of the mucous membranes with haemorrhage, and death from anaemia has been reported. Treatment locally by astringents and cautery is merely palliative, and the ideal procedure is to recognize and, if possible, remove the underlying causative condition. Becker considers that further intensive co-operative study will eliminate the group of essential generalized telangiectasia, and he believes that capillary study is a more valuable diagnostic means than gross morphological study.

#### 529. Treatment of Eczema with Sodium Thiosulphate.

B. THIRONE, L. S. VAN DYCK, E. MARPLES, and C. N. MEYERS (*Urol. and Cutan. Rev.*, September, 1926, p. 530) treated 104 cases of eczema by injections of sodium thiosulphate in doses of half a gram three times a week. In more than 80 per cent. of the cases prompt response to the treatment was obtained and the patient was able to resume his normal activities. All the patients in the series showed an abnormally high sugar and chloride content of the blood, and it would appear that there had been a deposition of these substances in the cutaneous layers. The authors think that the vesicular weeping condition is closely associated with the chloride content of the tissues, and that the pruritus is associated with the carbohydrate content. The patients usually responded to four or five injections. During the period of treatment the carbohydrate and chloride content of the diet was restricted. The first signs of clinical improvement were disappearance of the oedematous condition of the skin, which was followed in a few days by desquamation. Six illustrative cases are recorded.

#### 530. Congenital Partial Albinism.

V. PARDO-CASTELLO (*Arch. Derm. and Syph.*, August, 1926, p. 177) records four cases of partial albinism in a woman aged 32 and three children aged 4 years, 3 years, and 8 months respectively, all white, from direct Spanish ancestors, the possibility of admixture of coloured blood being carefully excluded. All presented extensive achromic patches of similar size and shape over the chest, abdomen, legs, and arms. In the first and second children several islets of pigment were distributed irregularly over the achromic patches. On the legs the leucoderma was irregular, alternating with pigmented spots. On the centre of the forehead and adjacent part of the scalp all showed a triangular leucodermic area on which the hair was white, in contrast with the light chestnut colour of the rest of the hair. The patients were normal in all other respects. The condition could be traced back to the maternal great-grandmother. There was no predilection for either sex, five females and six males being affected in each generation. Of the sixteen members of the family in these four generations only five were unaffected. Like Darier and others, congenital leucoderma evi.

## Obstetrics and Gynaecology.

#### 531. Uterine Retrodisplacement in Pregnancy and the Puerperium.

W. C. DANFORTH and C. E. GALLOWAY (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 826), from an analysis of 1,000 cases of women not engaged in hard work, maintain that the importance of retrodisplacement as a pathological entity has been grossly overestimated, and that far too many operations are performed for its correction. As a routine they ascertain in all pregnancies, unless gestation is far advanced, whether the uterus is displaced or not, and if so, subsequent examinations are made in order to find out if the uterus has spontaneously corrected its position and risen above the promontory. They regard this as being extremely important, since incarceration of this organ below the promontory must inevitably lead to abortion or to serious discomfort and possibly danger to the prospective mother. In women with no history of abortion nothing is done beyond

ascertaining the mobility of the retrodisplaced uterus; thereafter only periodical examinations are made to determine its ascent out of the pelvis, or its prevention from rising by the promontory. In the latter event the displacement is manually corrected. Simple manual reposition often suffices, but if this fails, the manoeuvre of Schulz is tried, and this simple means in the majority of cases is successful. After this a pessary of suitable size is employed until the uterus is too large to re-enter the pelvis; the patient remains in bed for two days, and is given half a grain of codeine at once and another in the evening, the manipulations being usually performed in the afternoon or late morning. Should this procedure fail an attempt at correction is made in the knee-chest position. When all these attempts fail anaesthesia becomes necessary. The authors claim that retrodisplacement of the uterus is not an important cause of sterility and abortion, and that surgical intervention is not warranted when no other reason for the operation exists; that these operations should not be performed without efforts to discover the cause of sterility; and that sterility may often be effectually cured by pessary treatment for a few months. Prevention and correction of retrodisplacement in the puerperium is, they add, important, and the obstetrician should supervise the process of involution. The authors describe their plan of treatment, and in conclusion state that about one woman in five in their series had retrodisplacement during pregnancy and the puerperium, and that retrodisplacement during pregnancy need cause little trouble provided that intelligent vigilance is exercised. In 29 per cent. of the cases reposition was performed and the uterus retained by a pessary; in the remainder correction ensued spontaneously. About 14 per cent. of the patients had a backward displacement of the uterus eight weeks after parturition. Reposition and retention in the anteфлекed position aids the process of involution but does not invariably cure the displacement permanently.

### 532. Syphilis of the Uterus.

C. AUDRY (*Paris Méd.*, October 9th, 1926, p. 277) asserts that utero-ovarian syphilis is frequent, very important, and almost always unrecognized, and that half the cases of cancer of the uterus develop in syphilitic patients. He has been surprised at the quantity of leucoplastic alterations revealed by microscopical examination of suspected metritis and cancerous cervixes. Many young females suffer from cervical or total metritis, with or without complications of the adnexa, and without any visible syphilitic symptoms or antecedents. A certain number of these patients show gonorrhoeal infection; others do not, but have instead a positive Wassermann reaction. The latter do not respond to the usual local applications for gonorrhoea, but even in the absence of all local measures specific antisyphilitic treatment is followed by rapid and complete cure, the preparation advocated by the author being novarsenobenzol. Audry lays stress on the considerable importance of syphilitic antecedents in the cases of cancer of the uterus, and believes that utero-ovarian syphilis is at least as common as, and probably more important than, urogenital syphilis in the male.

### 533. Diathermy in Cystitis and Cervicitis.

A. WASTERLAIN (*Le Scalpel*, September 25th, 1926, p. 871) states that cystitis in the female is often associated with a cervico-metritis, which may be gonorrhoeal. Treatment by the usual methods, such as caustics and glycerin dressings, is very slow, and exposes the bladder to risks of reinfection; excellent results have been obtained by diathermy. Wasterlain uses the apparatus of Heitz-Boyer No. 11, with a graduated delivery of up to 3,000 milliamperes. The author insists that restoration of the cervix to its normal condition can be obtained by diathermy alone without electro-coagulation, and attributes the cure of cervicitis and accompanying ulcerations to the fact that the adnexa were treated in the first place. He holds that it is logical in all treatment of cervicitis to direct the diathermic applications first to the adnexa, even in the absence of pain or swelling in these organs.

### 534. Inhibition of Uterine Contractions by Anaesthetics.

M. P. RUCKER (*Anesthesia and Analgesia*, October, 1926, p. 235) draws attention to the fact that in obstetrics two individuals are anaesthetized at once, and both the mother and the child have to be safeguarded. Drugs that are commonly used to alleviate labour pains roughly fall into two groups—analgesics, which are used in the first stage of labour, and anaesthetics, used in the second stage. As a result of his studies on the changes in intrauterine pressure brought about by these drugs, the author concludes that all analgesics and anaes-

thetics have some tendency to diminish uterine contractions. He ranks the analgesics in the following order in this regard: paraldehyde, magnesium sulphate, morphine, bromide, and chloral. Chloral alone has scarcely any effect, while hyoscine usually increases the force of the contractions. The general anaesthetics can be very definitely placed in the following order in reference to inhibitor action on uterine contractions: chloroform, ether, nitrous oxide-oxygen, and ethylene. Sacra anaesthesia with novocain inhibits the contractions when combined with adrenaline, but otherwise does not do so.

## Pathology.

### 535. The Haemoclastic Test.

G. ALTSCHULLER (*Strasbourg Med.*, July 5th, 1926, p. 272) states that the haemoclastic test is characterized by an abrupt rupture of the physico-chemical equilibrium of the secretions of the body; that the leucopenia and fall in blood pressure are only phenomena secondary to colloidal shock; and that in special conditions a typical shock can be produced without diminution in the blood pressure or number of leucocytes. The regulating mechanism of colloidal equilibrium of the blood and secretions is very complex. The liver, lungs, and the glands of the internal secretions play an important role in the production of shock; but it seems very probable that side by side with these organs of glandular structure there is a central nervous control over the colloids and crystalloids of the organism. According to the latest researches this centre lies in the floor of the third ventricle. The usual index of haemoclastic shock is the number of leucocytes, but Altschuller states that considerable modifications of the neutrophile table of Arneft also occur, and that this nuclear haemoclastic reaction is more constant and characteristic than the leucocytic one, and is, moreover, absolutely independent of variations in the number of leucocytes. Adrenaline and pilocarpine injected subcutaneously with the ingestion of milk provoke a leucopenia or leucocytosis without changing in the least the character of the nuclear crisis. In the place of 200 c.cm. of milk (Widal), the author administers glucose (1.5 gram per kilo of weight). The advantage of this method is that it is possible to study the reaction more closely by estimating the consecutive glycaemia.

### 536. The Relation of Bacterium pneumosintes to Influenza.

M. W. HALL (*Journ. Exper. Med.*, October, 1926, p. 539) has obtained confirmatory evidence of the original observations of Olitsky and Gates with regard to the association of *B. pneumosintes* and influenza. In February, 1922, there was an outbreak at Fort Myer, near Washington, of clinically typical influenza. From one of the cases of this epidemic nasopharyngeal washings were collected within twenty-four hours of the onset of the disease; they were thoroughly emulsified and injected intratracheally into one rabbit and two guinea-pigs. On the second day the rabbit showed a rise of temperature, a fall of 25 per cent. in the total leucocyte count and of 40 per cent. in the mononuclear count. The rabbit was killed, and at necropsy there was found a diffuse lesion of the lungs, which corresponded in many respects to that considered by Olitsky and Gates to be characteristic of infection with *B. pneumosintes*. The two guinea-pigs died, apparently as the result of the operative procedure, but another guinea-pig, which was injected subcutaneously, showed on the fourth day a fall of 40 per cent. in the leucocyte count; this animal was found to be suffering from a similar diffuse pulmonary lesion to that encountered in the rabbit. Another guinea-pig inoculated with the emulsified lungs of this animal showed a slight rise in temperature, a fall in the mononuclears, and a well marked diffuse lesion of the lungs. Cultures made from this animal on the Smith-Noguchi medium gave a growth of minute Gram-negative coccobacilli conforming to the descriptions of *B. pneumosintes*. The organism was maintained by weekly subcultures on blood agar plates incubated anaerobically. When injected into fresh animals it gave rise to the same reactions—namely, a rise in temperature, a fall in the leucocytes, especially of the mononuclear leucocytes, and a diffuse lesion of the lungs. Experiments made with this organism suggested that when injected into animals it led to the pulmonary localization of other bacteria with the production of definite pneumonia lesions; the secondary organisms (pneumococci) were injected intravenously on the day following that on which *B. pneumosintes* had been injected. Hall believes that his findings support the opinion that this organism is the primary infecting agent in influenza.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

537.

### Cardiac Epilepsy.

**L. MARCHAND** (*Paris Méd.*, October 19th, 1926, p. 307) states that the convulsive crisis appearing in the course of heart disease does not differ from an ordinary epileptic attack; it is a form of delayed epilepsy and rarely occurs before the age of 40. It may only show itself by transient loss of consciousness or vertigo. The attacks may be preceded or followed by mental disturbance, due either to circulatory failure or to secondary autointoxication. While the diagnosis of convulsions due to the Stokes-Adams syndrome is usually easy, this is not so with the epileptiform crises occurring in heart disease. Before making a diagnosis of cardiac epilepsy a thorough investigation of the renal condition is necessary to exclude uraemia. The epilepsy of arterio-sclerosis may also be confused with cardiac epilepsy. In arterio-sclerosis there is no connexion with symptoms of cardiac failure, and in many cases there are signs of focal cerebral sclerosis, and the epilepsy of cardiac origin be admitted it must be distinguished from hileptic epilepsy occurring in a case of heart disease. In the Stokes-Adams syndrome the epileptiform crises are due to cerebral anaemia; cardiac epilepsy is a rare form of symptomatic "late" epilepsy. The crises do not correspond directly with the cardiac failure, for they do not occur in cases of well compensated cardiac lesions. The attacks occur during periods of heart failure, whether this is due to an aortic or a mitral lesion or to myocardial disease. Any treatment that improves the heart condition usually relieves the convulsive attacks. The etiology varies in different cases; cerebral anaemia, autointoxication due to renal or hepatic complications, cerebral oedema, or a sudden fall of arterial pressure may cause an attack. There may also be a neuropathic tendency, or some cerebral lesions, due to alcoholism, lead poisoning, focal lesions, or old-standing disease, reactivated by autointoxication.

538.

### Prophylaxis of Whooping-cough.

**J. A. A. MUÑOZ** (*Arch. de med., cir. y esp.*, September 25th, 1926, p. 577) records his observations on 183 children, aged from eight days to a year, 161 of whom received prophylactic and 22 curative injections of anti-whooping-cough vaccine. For prophylaxis four injections were given every other day, the first consisting of 100 million organisms, the second of 200 million, the third of 400 million, and the fourth of 800 million. Most of the children showed a slight febrile reaction after the injection. The mortality of the cases was 7.6 per cent., fourteen deaths being due to bronchopneumonia; eleven of the fourteen deaths occurred among those who had not been given vaccine until whooping-cough developed, and three among those who had had prophylactic treatment. Muñoz concludes that the prophylactic vaccine treatment of whooping-cough deserves to be generally employed, especially in institutions and children's homes, since it prevents the risk of bronchopneumonia, which is so frequent in vaccinees. The course of the disease in cases treated by vaccine was not prolonged, but the results were not satisfactory in private practice the results were better. When vaccine prophylaxis is employed the probability of success is greater.

539.

### Anaphylactic Skin Reactions.

**T. LEWIS** and **R. T. GRANT** (*Heart*, September 29th, 1926, p. 219) describe the case of an asthmatic man, aged 49, who had suffered all his life from urticaria, always induced by ingestion of or contact with fish. Asthma and bronchitis had been present for twenty years, but the former was not growing worse. Eczema also had been troublesome for twenty years; handling fish or even using a fishy fork quickly produced a local attack. The authors studied the skin reaction of this patient to injury, to histamine, and to dilute fish extracts. Many cases of urticaria are more or less specific, and the skin is extremely sensitive to weak extracts of the sensitizing substance, which, when applied to the scarified skin, produce an urticarial wheal. An attempt was made to ascertain whether this anaphylactic whealing and the histamine reaction were identical with those of the histamine reaction. A single firm stroke on the skin did not produce a wheal, and histamine (1 in 3,000) introduced by cutaneous puncture produced only a normal reaction. The skin reaction to a number of grouped proteins was normal, but fish extracts produced local wheals, followed by local and general erythema and much discomfort. Pricking various fish extracts into the skin showed that it was most susceptible

to herring, less to smelt, and still less to cod and sole; there was little or no reaction to other species. The reaction to fish, like that to histamine, included a local active vascular dilatation, an arteriolar flush, certainly due to a local nervous reflex, and a local increased permeability of the vessel walls. When histamine and fish extract were tested simultaneously the two reactions were similar in all stages; flushes and wheals appeared almost simultaneously, but the fish reaction was slightly slower. The flushes and wheals subsided at the same rate. A normal subject was sensitized by the intradermal injection of 0.5 c.cm. of the patient's blood serum, and the skin resumed its healthy appearance within a few hours. Eighteen hours later this man ate a herring, and within an hour the area into which the serum had been injected was dark red and itching; it was surrounded by a widespread arteriolar flush, and the centre was raised into a prominent wheal. The reaction subsided slowly in twenty-four hours. In an attempt to isolate the toxic substance it was shown that it was not a coagulable protein, nor of the nature of histamine, but it appeared to be associated chiefly with nucleic acid. In the susceptible patient the fish substance was about 170 times as active as histamine. The authors conclude that the anaphylactic poison acts on the skin by liberating in it a histamine-like substance.

540.

### Chronic Cholecystitis without Gall Stones.

**M. CHIRAY, I. PAVET, and J. MARIE** (*Presse Méd.*, October 13th, 1926, p. 1281) state that the diagnosis of chronic non-lithiasic cholecystitis is very difficult, the clinical manifestations being very tardy, and the patient suffering for some time before seeking advice. Usually these patients have a long period of digestive troubles, which may be the cause, as well as the result, of gall-bladder infection. The most important among these troubles is constipation, and especially chronic intestinal stasis. Chronic amoebic dysentery is sometimes a cause, and the association of cholecystitis with appendicitis, typhoid, and paratyphoid fevers has long been known. The bacterial flora connected with this condition is varied. The enterococcus, streptococcus, staphylococcus, *B. coli*, *B. proteus*, and *B. paratyphoid* B play causal parts. There is some controversy as to the avenue of infection. The authors think that the infection of the gall bladder follows elimination of the bacteria by the liver; by many a haematogenous infection is traced. In this there may be a short circuit, the infection following the intestine-portal-hepatic route; the bacteria, leaving the intestine, invade the portal system and finally lodge in a hepatic lobule, from which they afterwards escape by the biliary ducts. There may also be a long systemic circulation, as in typhoid or paratyphoid fever. In treatment the authors rely mainly on Haarlem drops given in capsules two or three times a day before meals, and continued for ten or fifteen days. Hexamethylenetetramine is also administered in 7-grain cachets, one being given before each chief meal. Acute cases are treated with cold applications. Diet is of less importance than in lithiasis. The authors add that this treatment has met with great success, but, should it fail, drainage of the duct, either intermittent or subcutaneous, is indicated; they prefer the former. Should no benefit result from this, cholecystotomy should be performed.

541.

### Endocrine Changes in Congenital Syphilis.

**A. CANGE** (*Gaz. des Hôp.*, September 1st and 3rd, 1926, p. 1137) records the case of a girl, aged 11 years, who, in addition to characteristic lesions in the bones, dental dystrophies, and parenchymatous keratitis, presented Marañon's syndrome, which consists in acrocyanosis of the hands and feet, accompanied by dampness of the palms and a swelling of the soft tissues of the hands, and is attributed by Marañon to ovarian incompetence. The patient also showed signs of hypothyroidism, such as a pale and puffy face, apathy, and indifference.

542.

### Typhoid Nephritis.

**P. CARNOT, E. LIBERT, and M. BARIETY** (*Paris Méd.*, September 25th, 1926, p. 243) record a case in a boy, aged 14½, of typhoid septicaemia which presented the following features. The symptoms were confined to those of a primary haemorrhagic nephritis with lumbar pain and profuse haematuria. The case thus resembled the classical instances described by Amat, Gouget, Carschmann, and Meyer. The typhoid origin of the nephritis was established by cultivation of the blood, urine, and bile. There were no renal sequelae. Comparative study of the urine and bile showed that the excretion of typhoid bacilli in the bile commenced later but persisted longer than in the urine.

## Surgery.

### 553. Treatment of Pyloric Spasm in Infants.

W. F. SUERMONT (*Deut. Zeit. f. Chir.*, October, 1926, p. 340) reviews the literature and records his observations on twenty-two cases of pyloric spasm in infants—eighteen males and four females—on whom Rammstedt's operation was performed at the Leyden Surgical Clinic. Only one died, shortly after the operation, so that the mortality was 4.5 per cent. Ten were 3 to 4 weeks old, six 5 weeks, one 6 weeks, two 7 weeks, two 8 weeks, and one only 9 days. With the exception of the last seven cases, in which gas and oxygen was used, the anaesthetic employed was ether administered on an open mask. Feeding could be commenced immediately after the operation. Some children continued to vomit for the first few days after the operation, but usually the vomiting stopped in two or three days, while several children did not vomit at all. The average stay in hospital after the operation was about eleven days. The advantage of Rammstedt's operation, according to Suermond, is that it can be unreservedly advised in all cases in which the child is still in a good state of nutrition, since conservative treatment involves more dangers, such as infection and nutritional disturbance, and also requires a much longer time. In breast-fed infants immediate operation is all the more desirable as it is extremely important for the child that this mode of feeding should be maintained. In any case the operation is indicated when no noteworthy success has attended the trial of conservative treatment for a few days. It is desirable that the after-treatment should be undertaken in conjunction with a pediatricist.

### 554. Diagnosis of Cerebellar Tumours in Children.

M. CRITCHLEY (*Brit. Journ. Child. Dis.*, July-September, 1926, p. 165) states that the four main symptoms of cerebellar growths in children are, in order of occurrence, vomiting, headache, disorders of equilibration, and visual disturbances. Another occasional symptom is the "cerebellar fit," which is preceded by no aura or premonitory symptoms, but consists in generalized tonic rigidity of the entire musculature. The physical signs may be classified into those due to actual cerebellar disturbance, such as atonia, ataxia, and asthenia; those due to pressure upon adjacent structures, such as squint and paralysis of cranial nerves; and those due to generalized hydrocephalus, which include enlargement of the cranium and separation of the sutures. Tumours primarily pontine may be distinguished from tumours primarily cerebellar by the late occurrence of drowsiness, by the absence of dysphagia until a very late stage, by the early appearance and rapid development of papilloedema, the late occurrence of cranial nerve palsies and spasticity, and the rarity of sensory loss.

### 555. A Diagnostic Skin Test for Appendicitis.

E. M. LIVINGSTON (*Arch. of Surg.*, November, 1926, p. 630) believes that the study of cutaneous hyperæsthesia can be of considerable service in the diagnosis of appendicitis. The skin is picked up between the thumb and forefinger and pulled directly away from the abdomen until discomfort is felt. The amount of tension necessary is constant for the particular patient and is much decreased over diseased areas. In this way a skin triangle for appendicitis has been mapped out in the right iliac region, the three points being (1) the highest point of the iliac crest, (2) the right pubic spine, and (3) the umbilicus. The triangle does not correspond with any specific nerve distribution. It was found to have a diagnostic value in 86 per cent. of a series of 428 consecutive cases of acute appendicitis. Appendix colic and secondary involvement of the appendix in some other abdominal affections also responded to this test occasionally. Contrasting the value of this test with other cardinal points in the diagnosis of appendicitis, the author reports typical pain present in 75 per cent., pyrexia in 67 per cent., nausea or vomiting in 70 per cent., leucocytosis in 76 per cent., and localized rigidity in 59 per cent.

### 556. Salivary Calculi.

G. R. HARRISON (*Surg., Gynecol. and Obstet.*, October, 1926, p. 431) concludes, from an experience of twenty-seven cases, that calculi of the salivary glands and ducts are not very rare, and are of interest because of the difficulty in diagnosing them and the satisfactory results following timely removal. They are usually single, but may be multiple; they occur at all ages and in any of the glands, though the submaxillary is the one most frequently involved. Harrison classifies these patients as follows: (1) those complaining of pain and swelling in the gland or duct upon the ingestion of food; (2) those giving a history of sudden pain and swelling with fever, without any previous history of recurrent swelling; and (3) those

presenting a hard swelling fixing the tissue of the involved gland or duct with, frequently, cellulitis of the neck and suppuration. X-rays give positive information in from 75 to 80 per cent. of cases after repeated and careful examination. Treatment consists in removal of the calculi through an intra-oral incision if they are situated in the sublingual duct or gland, the anterior two-thirds of the submaxillary, or the buccal portion of the parotid ducts, but through an external incision if they are in the masseteric portion of the parotid duct, the parotid gland, or the posterior third of the submaxillary duct or the submaxillary gland. If stones are situated in either the sublingual or submaxillary gland extirpation of the gland is indicated, and in order to prevent fistula formation gland removal is sometimes advisable when the calculi are located in the ducts, especially when there is accompanying inflammation. Incisions must be made with great care because of the possibility of injury to motor nerves. Stones should be removed regardless of whether they are producing symptoms, because their presence is always a potential source of danger.

### 557. Accident and Tuberculosis.

TSCHMARKE (*Zentralbl. f. Chir.*, October 2nd, 1926, p. 2540) has made the following suggestions to guide the practitioner in determining whether a case of tuberculosis is due to an accident. The accident must be proved to have happened, and to have involved a part of the body affected with tuberculosis. The accident must have been so considerable as to compel the patient to seek medical advice at once or very soon afterwards. The patient must already have had a tuberculous focus in his body at the time of the accident. Aggravation of an already existing pulmonary or extrapulmonary tuberculosis by an accident is possible, but as a general rule primary tuberculosis cannot be caused by injury to the lungs. Metastatic pulmonary tuberculosis is extremely rare, but miliary tuberculosis is possible as a result of injury to a tuberculous focus. An interval of at least four to six weeks, and at most six months, must intervene between the accident and the appearance of a tuberculous affection; miliary and ocular tuberculosis are exceptions to this rule. The course of the disease must be uninterrupted. Inoculated tuberculosis is possible and must be regarded as an accident. A careful study of the previous history, critical estimation of the statements of the patient and witnesses of the accident, and consideration of the clinical, pathological, and experimental evidence, are necessary in deciding whether tuberculosis is due to an accident.

## Therapeutics.

### 558. Dangers of Sulpharsenobenzol Injections.

M. MOLHANT (*Le Scalpel*, October 9th, 1926, p. 919) has given more than 20,000 injections of sulpharsenobenzol, and describes the local and general dangers involved. The local complications are hæmatoma, abscess, necrosis, septicæmia, anaphylactic oedema, sclerosing myositis, sarcoid tumours due to foreign bodies, and post-traumatic syphilis. The author has not seen many of these complications after injections of aqueous or glucose solutions of sulpharsenobenzol. In sclerosing cystic or non-cystic myositis the muscle becomes indurated after repeated injections, and sometimes a yellowish fluid escapes when the needle is withdrawn. These symptoms usually disappear rapidly under treatment by baths and massage, and may usually be avoided by selecting fresh sites for the injections. Molhant has seen two cases of "aseptic abscess" due to the patient using too frequent and too hot baths; when these were discontinued and a few punctures made recovery was rapid. Local allergic reactions varied in intensity from a simple erythema round the site of injection to an acute indurated and extensive congestion. Some patients were found to be very intolerant of arsenobenzene, and a single minimal dose might cause such a reaction, or else nausea and pruritus. The author states that general complications may occur immediately or some hours after an injection. In the former case the patient begins to sneeze and cough; he becomes extremely distressed, with collapse, intense congestion of the skin, especially of the face, followed by pallor and vomiting. Occasionally the patient faints suddenly without warning, his colour is livid, cyanotic, pulse rapid and weak, and the extremities are cold; this is followed by vomiting. The author encountered these alarming symptoms only two or three times; they disappeared rapidly after the vomiting. He adds that they are likely to occur in goitre, particularly in the exophthalmic form; in patients subjected to a prolonged treatment with colloidal iodine, given intramuscularly; when a nervous diathesis is present with endocrine-sympathetic disturbance; in pregnancy; in febrile conditions; and in chronic erythrodermia, indicating previous arsenobenzol poisoning. Molhant

thinks that in all such cases the treatment should commence with a minimal dose, preferably in concentrated glucose solution. The doses should be repeated and very slowly increased, an effective dose being often reached only after ten or fifteen injections. The later reactions, due to chronic arsenobenzol poisoning, are delayed erythrodermia, arsenical neuritis, purpura haemorrhagica, and jaundice. Erythrodermia, which occurs in about 2 per cent. of cases, may be herpeticiform with much oedema; it may last for weeks or even months. Concentrated glucose solutions lessen the tendency to general and skin reactions. Molhant believes that true arsenical neuritis occurs in some cases, and that the patients may also suffer from herpes zoster. Purpura haemorrhagica occurs in about 1 per cent. of all cases and jaundice only once in over 500 cases.

#### 519. Pituitrin in Enuresis.

A. I. BLAU (*Med. Journ. and Record*, October 20th, 1926, p. 492) records the results of a study of 90 cases of enuresis in which a thorough physical examination and urinalysis were made. He considers that the average case shows no definite causative abnormality, and that in only a few with some associated local or general condition does its removal result in cure. A vesicular atony, especially of the sphincter, and probably a neurosis, apparently underlies the condition, and the majority of cases fall into the category of an essential enuresis. After treatment for several months with the drugs usually considered beneficial it was found that only a few responded, and in 15 of the cases the exclusive use of atropine gave no better results. Pituitary extract was then administered orally to 75 of the cases in gradually increasing doses from 1/10 to 1/4 grain, and in 54 this was augmented by 0.5 c.cm. of pituitrin hypodermically, three injections being given at three-day intervals. In 50 per cent. of the cases the enuresis was of more than two years' duration before treatment began. The best results were obtained in those receiving both oral and hypodermic administration, especially when three injections were given, almost 75 per cent. being either improved or cured, and since 10 of the injected patients never returned for observation it may be presumed from the experience of those who were followed up that the percentage was even higher. Of those treated orally only, about 35 per cent. were improved or cured. Blau concludes that pituitrin in the treatment of enuresis gives better results than any other therapeutic method.

#### 550. Codeine and Morphine as Hypotensors.

M. BONJOUR (*Presse Méd.*, October 13th, 1926, p. 1283) details the excellent results obtained from the use of codeine and morphine in four cases—two of heart disease, one of total insomnia, and one of incontinence of urine—which did not respond to the usual treatment. These cases demonstrated the special value of opiates as remarkably sure hypotensors where other drugs had proved inefficacious. He finds them of particular value in cases of arrhythmia and pulsus alternans, but they can only be prescribed if the kidneys are healthy. The initial dose should be 1/60 to 1/30 grain a day; this is gradually increased each day or two until the desired effect is obtained. According to the conditions and the age, codeine or morphine, or a mixture of the two, is employed. This mixture was also found valuable in relieving the hypotension of the menopause, and its nervous and vasomotor troubles.

#### 551. Bismuth Treatment of Neuro-syphilis.

H. SÆTHRE (*Norsk Mag. f. Lægervidensk.*, September, 1926, p. 773) records his experience of the treatment by bismuth, in the form of trepol, bismogenol, and vioclin, of 79 cases of neuro-syphilis, among which were included 30 cases of tabes, 11 of general paralysis, and 4 of congenital syphilis. The total number of injections given was 2,091. The results were as follows: In general paralysis and congenital neuro-syphilis no clinical improvement was seen, the only effect being an amelioration of the findings in the cerebro-spinal fluid. Of 14 tabetic patients treated only by bismuth all but one showed great improvement, especially as regards the relief of pain, numbness, urinary disturbances, and ataxia. In five cases symptoms returned, and two proved refractory to further treatment. The Wassermann reaction in the blood was negative before treatment in 6 of the 14 cases; after treatment 12 were negative, while 2 remained positive. The spinal fluid became normal in one case, and in the others the use of bismuth reduced the reactions with persistence only of the Lange and a faintly positive Wassermann reaction in most of them. Among 12 other cases of neuro-syphilis 9 showed rapid recovery apart from pupillary disturbances and anomalies of the reflexes, and all the 9 cases but one showed negative reactions in their blood and cerebro-spinal fluid. In 38 cases bismuth was associated with other antisyphilitic remedies such as hectine or salvarsan, but the results were inconclusive.

## Neurology and Psychology.

### 552. Mental Deficiency and Congenital Syphilis.

N. A. DAYTON (*Journ. Amer. Med. Assoc.*, September 18th, 1926, p. 507) from previous investigations had concluded that congenital syphilis was the cause of mental deficiency in only a few cases. A further study of the intelligence of sixty-one mentally defective patients who were subjects of congenital syphilis showed that it was definitely superior to that in 1,956 cases of mental defect due to other causes. When congenital syphilis initiated the pathological process resulting in mental deficiency, the process was less severe and a higher average of intelligence was attained than in cases of mental deficiency due to other causes. From the statistical point of view congenital syphilis does not produce large numbers of cases of mental deficiency; nor does congenital syphilis produce a low grade of defect. Dayton therefore asserts that congenital syphilis is not a serious factor in the production of mental deficiency.

### 553. General Paralysis of the Insane.

A. SÉZARY and A. BARBE (*Paris Méd.*, October 2nd, 1926, p. 258) comment on the frequent variations in the progress of general paralysis of the insane. Life may be prolonged for two or three years or the disease may prove fatal in a few months. In other cases remissions occur spontaneously or after treatment. The authors find that stovarsol is far superior therapeutically to all other agents, including bismuth, and that sodium nucleinate, mesothorium, zinc oxide, camphorated oil, iodo-quinine, sodium uranate, and dinitrophenol are seemingly useless. Changes in the serological reactions do not appear to reflect clinical improvement in cases of general paralysis of the insane. The symptoms may improve while the reactions become accentuated, and conversely the symptoms may become more grave while the reactions approach the normal. This appears to indicate that meningitis is of secondary importance in the etiology of general paralysis of the insane. The undoubted improvement which is produced by some treatments must be regarded only as prolonged remission. In these cases the meningeal infective process may, indeed, be aggravated. Definite and lasting attenuations of serological modifications are only found in patients who have been treated with stovarsol or with malarial parasites; this shows that even if these treatments do not cure the condition, they have an undeniable action on the morbid process in the nervous system.

### 554. Psychoses in Encephalitis.

J. KASANIN and J. N. PETERSEN (*Journ. Nerv. and Mental Dis.*, October, 1926, p. 352) give notes of four cases of epidemic encephalitis in which a psychosis was the earliest clinical picture, neurological signs developing later. In one case an affective stupor was diagnosed, the patient being confused and wandering about in a dazed condition, refusing food, and having written farewell letters to her children. Two other patients showed signs of the manic type characterized by overactivity, flight of ideas, and distractibility, while the fourth was diagnosed as schizophrenia. The neurological signs were varied, three of the four cases showing a divergent sign, transitory tremors, and jerky movements of the extremities. A leucocytosis varying from 10,000 to 30,000 per c.c.m. was present in all four, and the sugar content in the cerebro-spinal fluid was increased; the colloidal gold reaction showed the usual range of variation. Xanthochromia was present in one case, and the Wassermann reactions of the blood and cerebro-spinal fluid were negative in all. The authors point to the possibility that many non-fatal cases of milder onset may retain as a residuum a psychosis which on later examination may be diagnosed as dementia praecox or manic-depressive insanity, and that a review of some of the early histories of atypical cases of schizophrenia or affective disorders may reveal a previous encephalitis.

## Obstetrics and Gynaecology.

### 555. Albuminuria in Pregnancy.

The albuminuria of pregnancy, pre-eclamptic toxæmia, and eclampsia are, according to A. J. CUNNINGHAM (*Med. Journ. of Australia*, September 11th, 1926, p. 331), different stages of one disease, and he associates with them chronic interstitial nephritis and uræmia, so as to form three large groups—nephritis and uræmia, of pregnancy, nephritic toxæmia, namely, the albuminuria of pregnancy, of pregnancy and uræmia. He describes the albuminuria of pregnancy as being a profound toxæmia of unknown origin, with an action resembling that of the poisonous albumins, proteoses, and albuminoses. In toxæmia without nephritis the systolic blood pressure may be from 130 mm. of mercury, rising in pre-eclamptic and eclamptic stages even to 200 mm. It

nephritic toxæmia while the figures are similar the variations are smaller; in uræmia the pressure is higher, over 200 mm. These figures are fairly constant, but may be upset in three ways. In actual convulsions the readings will be very high in all three; after accidental hæmorrhage and in heart failure they will be lowered. Blood-pressure readings every two hours or more often are very valuable in showing the onset of pre-eclamptic and eclamptic stages, the rise of pressure in many instances occurring before the severe symptoms appear. Any rise or continuation of high pressure post partum should suggest the onset of convulsions. If the high pressure persists it indicates drainage to the kidneys, but a fall to normal may occur in spite of such a condition. A rising pressure in spite of treatment, or a sudden rise, is an indication for active intervention. The blood urea content is usually low in the later months of pregnancy, less than 20 mg. per 100 c.cm. of blood; its estimation distinguishes between the three classes of albuminuria. In a true toxæmia it is normal, 20 to 40 mg.; in nephritic toxæmia it is higher, 50 to 100 mg.; and in uræmia 250 mg. Estimation of the blood urea is in some cases the only means of assessing damage to the kidneys and of giving a prognosis. A blood urea figure of over 50 mg. is an indication for the termination of pregnancy. Careful ante-natal supervision is essential, but in spite of it induction has to be performed in a large proportion of cases even in the first stage. In the pre-eclamptic stage, if it is not possible to induce labour at once, the author uses veratrine, either alone or combined with morphine, the pulse and blood pressure being carefully watched during its administration. In the eclamptic stage Cunningham advises conservative methods and a minimum of interference; to control convulsions he uses chloroform sparingly and avoids ether because of the risk of pulmonary oedema.

#### 556. Lipiodol in Diagnosis of Female Sterility.

L. M. RANDALL (*Amer. Journ. Obstet. and Gynecol.*, September, 1926, p. 326) advocates the use of lipiodol as an adjunct to tubal inflation in the diagnosis of sterility. Inflation alone will prove whether the Fallopian tubes are normally patent, stenosed, or entirely occluded, but the actual site of the lesion can be visualized by the injection of lipiodol, a chemical compound of 40 per cent. iodine in poppy-seed oil, which is opaque to x rays, non-caustic, and non-toxic. The injection is simple and painless, and affords a sharp shadow of the cavity of the uterus and the lumen of the tubes. Randall advises its use midway between the menstrual periods, and points out that the indications for it are the same as those for inflation, the contraindications being infection or hæmorrhage. The method seems to be particularly valuable when with non-patent tubes bimanual examination of the uterus and the history do not provide evidence of pelvic disease, and the question of surgical treatment is under consideration. Notes of three cases are given illustrating the value of the method in determining suitability for operation, and it is added that it is unjustifiable to subject apparently normal women, whose primary complaint is sterility, to an operation without giving them the benefit of as accurate a diagnosis as possible. If the site of closure can be located in a given case the value of an operation can be better determined, since the prospect of success is not good when the obstruction is in the narrowed portion of the tube, but is fair when the lesion is at the fimbriated end, which is the more common finding.

#### 557. Treatment of Post-partum Bleeding.

G. MÜLLER (*Gynéc. et Obstét.*, 1926, xiv, 3, p. 151) recommends Henkel's procedure in treating severe bleeding following childbirth. The patient is placed on her back with the lower limbs raised and abducted. A speculum is introduced to depress the fourchette and posterior vaginal wall, and the cervix is drawn downwards as far as possible towards the vulva by two volsella applied respectively to the anterior and posterior cervical lips. The cervix is now drawn forcibly to the left, and with a third volsellum a wide grip is taken of the right parametrium and cervical musculature. The cervix having been drawn to the right a fourth volsellum is now applied similarly on the left side. Lastly, the first two volsella are removed and the vagina is lightly packed. The purpose of the prolonged application of the third and fourth volsella is twofold: by temporarily fixing the cervix in a pulled-down position to induce a compression by angulation of the uterine arteries, and, secondly, to secure a direct compression of these vessels between the blades of the instruments. Henkel's technique is said to be specially useful in hæmorrhages following tears of the cervix or low insertion of the placenta; it is useless if a cervical tear has extended into the parametrium. Müller describes six cases of speedy arrest of hæmorrhage by Henkel's method: the volsella were removed after twenty hours, and no vesical, ureteral, or intestinal complications were noted.

## Pathology.

### 558. Focal Infection and Disease.

J. A. KOLMER (*Journ. Amer. Med. Assoc.*, September 11th, 1926, p. 824) holds that 80 to 90 per cent. of all deaths are due to some type of infection, and the acute specific infections are responsible for but a small part of these. Infections of the apices of the teeth, the nasal accessory sinuses, tonsils, and bronchi are the most important foci in adults. Even in cases of gall-bladder and bile-duct infection, infections of the upper respiratory tract are of primary importance, being followed by secondary infection of the intestinal tract and biliary passages through the swallowing of purulent material or by direct blood-stream infection of the liver. In the arthritis believed to be due to organisms or their toxins absorbed from the intestines the possibility of primary foci in the upper respiratory tract must be kept in mind. The genital organs, and particularly infections of the prostate gland and adnexa, are specially important in relation to the production of gonococcal arthritis, tenosynovitis, and endocarditis. Of all the organisms responsible for focal infection the group of streptococci is undoubtedly the most important, followed in order by the staphylococcus, pneumococcus, gonococcus, and colon bacillus, but the possible importance of the influenza and diphtheroid bacilli, as well as some of the specific organisms, as the tubercle and typhoid bacilli and the *Spirochaeta pallida*, in establishing primary foci from which distant organs may be secondarily infected, is also to be remembered. Kolmer considers that secondary foci in general are due to the presence of the organisms themselves rather than to their toxins, but that bacterial toxic substances may produce psychoses and neuroses, and be responsible in part for allergic sensitization, as in bronchial asthma, nervous rhinitis, and some skin diseases. The distribution of organisms and their toxins is largely by the blood. Absorption into the lymph draining the primary focus probably occurs first, and is responsible for secondary foci situated in the direct line of drainage, but transference to more distant organs is most certainly by way of the blood. The author holds that the importance of acquired selective tissue affinity on the part of the organism in secondary infection has been greatly overestimated, and that the main determining factors are the general virulence of the organism, local tissue immunity, hereditary influences, and trauma in a broad sense; the matter of secondary localizations or lesions in focal infection involves not only the virulence and numbers of organisms gaining access to the circulating blood, but also the kind and degree of local resistance about the primary foci, the degree of systemic humoral and cellular resistance, and the predisposition to secondary infection by anatomical defects and the presence of areas of inherited or acquired reduced tissue resistance. Exacerbation of secondary foci on the removal of primary ones is strong presumptive evidence of the relation between the two foci, and the determination of the virulence of the organism and its elective localization in the corresponding organs of some lower animal may aid in diagnosis.

### 559. Reported Isolation of *Brucella abortus* from Patients with Undulant Fever.

C. M. CARPENTER (*Journ. Infec. Dis.*, September, 1926, pp. 215 and 220) examined twenty cases of fever with symptoms suggesting Malta fever, and succeeded in cultivating from five of them a bacillus of the *Brucella* group. Tests made by direct agglutination and by absorption of agglutinins led the author to believe that the strains were not *B. melitensis* but *B. abortus*; though, since many workers have been quite unable to distinguish these organisms by these tests, it seems doubtful whether this conclusion is justifiable. The interesting point lies in their pathogenicity to cattle. The five strains were tested for virulence by intravenous injection into five pregnant heifers; all the animals aborted in from four to twenty days. The organism was recovered from the placenta and milk in each case; four of the foetuses that were examined likewise contained the bacillus. One of the cows discharged infective milk for six and a half months; she was then destroyed. A calf that was suckled by this cow remained infected for four months after its last feed, as evidenced by a high agglutinin titre and the presence of *B. abortus* in many of the glands. The virulence of these human strains would appear to be higher than of those isolated from bovine sources. Five of the patients from whom the organism was recovered were examined for serum agglutinins to *B. abortus*; in three of them a titre to this organism of 1 in 30 to 1 in 840 was found; in the other two no agglutinins were detectable. On the other hand, in two patients suffering from fever in whom the organism was not found, agglutinins to *B. abortus* were present. The author concludes that the agglutination test cannot be relied on to detect the presence of this organism in man.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 560. Mechanical Treatment in Anterior Poliomyelitis.

C. C. CHATTERTON (*Minnesota Med.*, November, 1926, p. 625) describes the treatment of anterior poliomyelitis in three stages: (1) The acute, which lasts from the time of onset until the neuritis and myositis disappear—a period of days or months; (2) the improving, beginning when the neuritis and myositis have disappeared, and extending over at least two years; and (3) the surgical, beginning at least two years after the acute attack. The author discusses in particular mechanical treatment, including physiotherapy, warmth, and exercises. In the second or improving stage, the fever has subsided in the acute stage, the patient is usually paralysed in one or more limbs, which are tender to the touch and painful on motion, while the general condition is below par. The principle of treatment should be rest and protection until all signs of tenderness have disappeared. At the end of the acute stage a full and complete test should be made of the damage to each muscle or group of muscles. If deformity is present it should be corrected gently by suitable apparatus; this should be simple and easily applied, and afford stability to the extremities and spine. Another form of apparatus is equally necessary. Massage undoubtedly increases the blood and lymph supply, carries heat to the tissues, improves muscle tone, and may prevent deformities. Extra warmth, secured by means of additional and woollen clothing, hot baths, and radiant heat through electric lamps, is of special importance. Exercises without weight-bearing are of great value; and swimming in brine tanks and horse-back riding are often beneficial. Chatterton asserts that when the apparatus, rest, massage, extra warmth, and exercises are conscientiously used good results may be expected.

561.

### Epilepsy and Spasmodic Torticollis.

L. MARCHAND and L. BAUER (*Rev. Neurolog.*, October, 1926, p. 310) observe that the occurrence of spasmodic torticollis among epileptics has been recognized for many years. Several cases have been reported, but only of the intermittent form, occurring at the crises and associated then with other convulsive symptoms. Cruchet distinguished three varieties of spasmodic torticollis in epileptic patients; in the first group spasmodic torticollis was only one of the localizing symptoms of the epileptic crisis; in the second group it represented an epileptic attack; in the third group spasmodic torticollis might occur in a patient who was also an epileptic, without there being any connexion between the two diseases. The majority of cases of spasmodic torticollis are of mental origin, but it may also be due to organic disease of the muscles, joints, or bones, or to certain lesions of the nervous system. Babiniski has described cases of spasmodic torticollis in which there was evidence of disease of the pyramidal tracts, especially of the cervical portions; later he came to the conclusion that the mesencephalic nuclei were involved. Pierre Marie and Lévi have drawn attention to the frequent occurrence of osteo-arthritis lesions in the cervical region, causing irritation of the cervical plexus, especially of the fifth and sixth cervical roots. Other writers have suggested that cervical articular rheumatism is secondary to the deformity produced by the torticollis. Three cases are mentioned in support of the theory of the mesencephalic origin of spasmodic torticollis. (1) A man, aged 34, had suffered from right spasmodic torticollis since the age of 5 months, and history of epilepsy and minor epilepsy occurred, and his mental development was that of a child aged 7. (2) A boy, aged 14, had suffered from left spasmodic torticollis since the age of 17 months, and from epilepsy since he was 5½ years old. There was no family history, except that his maternal grandfather was an inebriate, and no evidence of syphilis. He had frequent attacks of major epilepsy, and his intelligence was that of a child aged 6. The clavicular origin of the sterno-mastoid muscle was divided, but no appreciable improvement followed. (3) A man, aged 31, had suffered from spasmodic torticollis since the age of 9 months; convulsive epilepsy commenced in his tenth year. No evidence of syphilis was present. From childhood he was stubborn and self-willed; as an adult he could not work, and his intelligence was that of a child aged 7. His speech was hesitating and spasmodic. The reflexes were normal, but he dragged the right foot slightly

when walking. The authors observe that the three patients were males, that in two cases the torticollis affected the right side, in one the left; it was permanent and tonic. In two cases it followed infantile convulsions, in the other case there was no apparent cause. The early appearance is opposed to the theory of a mental origin, and the neurological symptoms suggested derangement of the motor tracts. All three patients exhibited advanced mental deterioration, and in each epilepsy supervened long after the torticollis appeared. The mental deterioration suggests a more or less diffuse cortical sclerosis. If there were no symptoms of a lesion of the pyramidal tracts facial contractures and spasticity of a limb suggested a mesencephalic lesion, especially of the corpus striatum.

562.

### Exanthema Subitum.

H. BUSCHMANN (*Med. Klin.*, July 23rd, 1926, p. 1146) records four cases in children, aged from 7 months to 3½ years, of the eruptive fever described by Veeder and Hempelmann under the name "exanthema subitum," of which only nineteen cases have hitherto been reported in German literature (von Bokay, Leiner, Salomon, and Engel; see *Epitome*, December 19th, 1925, para. 558; February 27th, 1926, para. 229). The onset is acute, the temperature rising to 104.8° without much constitutional disturbance, and remaining high for three to five days. The rash, which appears as the temperature falls and lasts about four days, is a morbilliform eruption chiefly affecting the trunk without involving the mucous membranes to any extent. The blood picture is typical, being characterized by leucopenia (3,000 white cells, with 80 to 85 per cent. lymphocytes and no change in Arneith's formula. As soon as the temperature falls the number of leucocytes rises and the lymphocytosis decreases. No special treatment is required, as the disease runs a very mild course, and no complications or sequels have been observed.

## Surgery.

563.

### Splenectomy for Purpura Haemorrhagica.

As E. BEER (*Annals of Surgery*, October, 1926, p. 549) remarks, the growth of knowledge about the forms of purpura and their treatment by splenectomy has been very rapid. The main characteristic of the disease appears to be a diminution of the number of blood platelets and the absence of contraction of the clot with the usual expression of serum. It was found that removal of the spleen both in man and animals brought about a definite increase in the number of blood platelets, and this opened the way for splenectomy in cases of purpura. The disease itself seems to take one of two very different courses. In the chronic or relapsing type splenectomy appears to be particularly useful. The acute type is more rapidly progressing and splenectomy in these cases is of questionable value. The disease is not hereditary. It occurs in the young, and haemorrhages may appear in all parts of the body as small petechiae and external bleeding. In these patients there is a low platelet count, whereas in haemophilia the platelets are not reduced. After splenectomy the platelet count rises, but usually drops again to near the level before operation. Beer records five typical cases treated by splenectomy; four were of the chronic variety, and the result followed soon after operation. In the one acute case a fatal

### 564. Primary Tuberculosis of the Mesenteric Glands.

M. METTENLEITER (*Deut. Zeit. f. Chir.*, October, 1926, p. 120) during the last ten years has seen thirty-three examples of primary tuberculosis of the mesenteric glands in children at the surgical department of the municipal hospital at Erfurt. The disease is therefore more frequent than is generally supposed, children between the ages of 10 and 15 being most frequently affected. An acute and a chronic form may be distinguished. The diagnosis can readily be made when a tumour is distinctly palpable, but a confusion between appendicitis and the acute form is possible. In chronic cases affection of the mediastinal glands is a much more likely occurrence than chronic appendicitis. The patient's general condition is an important feature in differential diagnosis. Patients suffering from appendicitis almost always show signs of being severely ill, while subjects of mesenteric tuberculosis feel well in spite of their pain. The disease usually runs a favourable course, and only slight symptoms

are caused even by considerable enlargement of the glands. Of Mettenleiter's thirty-three patients twenty-nine underwent operation, when the appendix with one exception was found to be normal: in four cases the diagnosis was made by the presence of a palpable tumour. All the patients made an uncomplicated recovery. After-treatment consisted in artificial sunlight and application of x rays.

565.

**Sciatica.**

A. E. HERTZLER (*Amer. Journ. Surg.*, October, 1926, p. 200) defines sciatica as a painful affection of the sciatic nerve due to conditions within the nerve produced by unknown causes, and lesions adjacent to the nerve. A common prelude to sciatica is a painful affection of the sacro-lumbar region. The onset often follows unusually strenuous labour or sudden movements. The pain may be explained by a synovitis of the sacro-iliac joint; since the nerve lies over this joint the joint inflammation may produce irritation of the nerve. When associated with lesions of the joint the symptoms begin with great intensity in some cases, or they may come on gradually. Before the diagnosis of sciatica is made a complete examination of the patient is necessary, and disease of the nervous system and affections causing pressure on the nerve must be excluded. Hertzler states that stretching of the nerve by the bloodless method gives only indifferent results. The injection of fluids in or about the nerve has been practised for many years, and the author finds that the use of 1 per cent. solution of quinine and urea hydrochloride is a specific for sciatica. The nerve is injected where it crosses the neck of the femur. A single injection is sometimes sufficient, but usually several are required. He adds that the condition does not recur after this form of treatment, and that complications are rarely encountered.

566.

**Spontaneous Gangrene in Syphilis.**

F. KAZDA (*Deut. Zeit. f. Chir.*, October, 1926, p. 74), who records two illustrative cases with a review of the literature, discusses the question of the influence of syphilis on the development of so-called "spontaneous gangrene." His conclusions are as follows: (1) It has not yet been determined how far syphilis is responsible for the development of an arterio-sclerosis which can lead to gangrene, although the possibility of this connexion was conceived by Virchow. (2) The influence of syphilis on the development of endarteritis obliterans was at first denied, later accepted, and recently again doubted. (3) Late syphilis has the power to produce changes in the peripheral vessels which may give rise to trophic disturbances. There is no proof that syphilis can produce a true, purely spastic Raynaud's disease. (4) Very little is known of changes in the peripheral vessels caused by syphilis in the form of non-specific mesarteritis or periarteritis, or of multiple gummata of the vessel wall leading to gangrene. (5) There are, however, vascular changes in the extremities caused by syphilis which may lead to gangrene. Anatomically two types may be described—namely, multiple gummata in the vessel wall, and infiltrations of lymphocytes and plasma cells, principally in the media and adventitia. The clinical course of such cases is characterized by short prodromes of an angio-spastic character in a syphilitic subject, attacks of pain which are often extremely violent and of a neuralgic character, the appearance of gangrene and ulceration, rapid change in the coloration of the peripheral part of the affected extremity, simultaneous involvement of several extremities, and relative mildness of the process. The frequency of such conditions appears to be much greater than the very few cases on record suggest. Treatment consists in vigorous antisymphilitic therapy. The prospect of recovery is good in cases where large vessels have not been obliterated.

## Therapeutics.

567.

**Strophanthus and Renal Disease.**

L. GRAVIER (*Journ. de Méd. de Lyon*, October 5th, 1926, p. 491) finds that strophanthus, strophanthine, and ouabaine have a direct action on the kidney, like that of cantharides; this explains the oliguria, haematuria, and lumbar pain which occasionally follow the intravenous injection, and justifies the warnings regarding the use of these drugs in cases of renal disease. Gravier states that Bright's disease is not, however, an absolute contraindication, and these patients need not be deprived of the cardiotonic effects of strophanthus or of ouabaine, but it is necessary to use these drugs in minimal doses. In doses of 1/8 to 1/4 mg., ouabaine may be very useful in Bright's disease, as in heart disease, although it is necessary to guard against serious effects. Neither the mode of elimination of these drugs nor their toxic action is fully understood, but the rapidity with which serious

symptoms sometimes follow the intravenous injection of strophanthine (in about thirty to sixty minutes) leaves little doubt that the renal factor plays an important part. It has been stated that these drugs cause renal hyperaemia and lesions of the cells of the convoluted tubules, similar to those produced by cantharides. Gravier describes the case of a woman, aged 59, who suffered from chronic nephritis with hypertension (240/140 mm. Hg). The patient was treated at Royat and Vichy, but on her return to Lyon, she suffered from slight attacks of pulmonary oedema and dyspnoea. She received an intravenous injection of 1/4 mg. of ouabaine, and fifteen minutes later had a violent attack of lumbar pain accompanied by oliguria. The treatment was discontinued and lumbar wet cupping was substituted in addition to hot baths; this treatment produced moderate diuresis. The author concludes that for the kidney, as for the heart, the margin of safety of both strophanthus and ouabaine is very narrow. The effective dose is very nearly toxic, but under careful supervision these drugs may yield good results in both cardiac and renal cases when minimal doses (1/10 to 1/4 mg.) are employed.

568.

**Iodine in Exophthalmic Goitre.**

To illustrate the good effects resulting from the use of iodine J. SLOSSE (*Bruxelles-méd.*, November 1st, 1926, p. 17) cites five cases which showed the cardinal symptoms of exophthalmic goitre—tachycardia, nervous and emotional symptoms, exophthalmos, loss of weight and energy, and increase in the respiratory exchanges. The patients' ages ranged from 22 to 61 and treatment consisted in the daily administration of 30 drops of Lugol's solution (5 per cent. iodine and 10 per cent. potassium iodide). With this method all the patients markedly improved, showing a lessening of basal metabolism, a rapid diminution of the cardiac pulsations, and an increase in weight. Slosse claims that this treatment is applicable only in cases of actual Graves's disease, and distinguishes between this and a closely related condition, toxic adenoma or adenoma with hyperthyroidism. While these two conditions have many characters in common, there are important diagnostic differences, a fundamental one being the type of nervousness. In Graves's disease there are small movements such as frequent changing of position, crossing of the legs, and adjusting of different parts of the dress—symptoms which are never exhibited in toxic adenoma. In the latter condition also, though the gland increases bilaterally, there is asymmetry in its development, and on palpation one or more resistant nodules are felt. In Graves's disease the gland not only develops bilaterally, but also symmetrically, a cardiac souffle can always be heard at the upper and lower poles of the gland, and to the palpating finger the gland feels soft and gives a thrill sensation. Finally, in Graves's disease the respiratory exchanges are more raised than in toxic adenoma. Concerning the length of treatment, the author states that in the majority of cases the nervous symptoms are ameliorated and the tachycardia and basal metabolism lessened in twelve to fifteen days, certainly in three weeks, and that this treatment is an excellent preparation for surgical intervention. Slosse adds that basal metabolism provides the criterion for the diagnosis and treatment of thyroid affections.

569.

**Congestion Treatment of Chilblains.**

L. J. C. MITCHELL (*Med. Journ. of Australia*, October 2nd, 1926, p. 449) believes that the blood state is a factor in the causation of chilblains, as is evidenced by the improvement after treatment with calcium salts, and that this condition is a vasomotor disturbance with a curious patchy distribution. The parts mostly affected are the dorsal aspects of the fingers and toes and the margin of the external ear, while the tip of the nose, the outer aspects of the fifth metatarsophalangeal joints, and the internal posterior and external aspects of the heel are more rarely attacked. At all these points there is a minimum of subcutaneous fat, the skin, tendon, and sheath being practically the only covering of the bone or cartilage. These considerations led the author to think that any method of congesting the parts would relieve the condition, and he accordingly tried Bier's congestive treatment. Congestion was obtained by applying a few turns of a 2½ in. rubber band just below the knee or just above the elbow over a stocking or the underwear, with just enough tension to be felt but not cause pain. This gave relief, and after continuous wear would clear up the most obstinate crop of chilblains. Mitchell holds that the elastic pressure in conjunction with muscular movement and with arterial pulsation provides continuous massage which keeps the blood and lymph in these areas on the move, and so the lesions are cured. Three days sufficed to banish all swelling, and the only untoward consequence was the possibility of accelerating the development of varicose veins. The author now uses gum-rubber tubing of the weight of medium surgical gloves. Lengths of 3/4 to 1 in. are cut, and the band

obtained is stretched over the affected part at its greatest thickness. A sock is then put on, and the hand stays in place whether the body is at rest or not. The hands are best treated by the wearing of rubber gloves at night only, but these must fit firmly. The toes can be treated by the cuff of the rubber glove worn round the foot or by a thin piece of sponge rubber held firmly in place by sticking-plaster. Pressure must be firm but not painful. Breaking of the skin does not preclude the use of the method. In this event the area is cleaned, dusted with borie powder, and covered with a thin piece of flat, over which the hand is applied. Relief from the itching and throbbing is said to be instantaneous, and after a day or two the part is normal in appearance save for a little desquamation.

## Laryngology and Otology.

570.

### Influenzal Laryngitis.

M. CASSAC (*Rev. de Laryngol.*, October 15th, 1926, p. 571) has drawn up the following classification of the varieties of influenzal laryngitis. (1) The acute catarrhal form presents the symptoms and course of ordinary acute catarrhal laryngitis. (2) The infiltrative oedematous form presents one of the most frequent varieties, and is characterized by a sensation of obstruction or pricking in the pharynx or larynx, and particularly by violent pain on swallowing and phonation. These symptoms increase towards 4 or 5 p.m., are accompanied by difficulty in breathing, and reach their height about midnight. Towards morning the symptoms decrease and almost completely disappear. (3) The ulcerative form is difficult to diagnose from tuberculous laryngitis; a distinction is made by the history and course of the disease and by the general condition of the patient and his antecedents. In mild cases small superficial ulcers are found at the posterior insertion or less frequently on the anterior third of the vocal cords. In the more severe forms the ulcers are deeper and may invade the whole extent of the vocal cords. The lesions are usually bilateral. This form is very refractory to treatment, especially in persons who have to make use of their voice. (4) The phlegmonous form is the first stage of an infection which will give rise to an intralaryngeal abscess; it may become absorbed or open spontaneously. (5) In the necrotic form the perichondritis may be localized to the thyroid or cricoid cartilage, or the whole of the larynx and trachea may be involved, death occurring in three or four days. Local treatment will vary in each case; in some instances both medical and surgical measures will be required.

571.

### Local Applications of Vaccine in Otology.

J. HELMOORTL (*Le Scalpel*, September 18th, 1926, p. 851) describes the treatment of furuncles of the nose and of the auditory meatus by means of vaccine, and the post-operative treatment of mastoid abscess with vaccine and with the antiserum of Bertrand. In treating furuncles the cuticle is first removed by applying carbolic acid in glycerin for six hours. At the end of this time the cuticle can be peeled off readily. The carbolic acid acts as a disinfectant. The vaccine is then applied on pieces of cotton-wool in the depths of the meatus or nose. The dressing is repeated until all the furuncles have disappeared and for a short time afterwards. The vaccine is almost unknown. A number of cases are recorded in which the cavity of a mastoid operation has been dressed for a few days with balsam of Peru and then with the vaccine, with very rapid and satisfactory electrization. A more severe case developed erysipelas, and the plaque of erysipelas was painted with the antiserum of Bertrand (two-thirds antiserum and one-third antistaphylococcus). An abscess formed in the deeper parts of the neck and was treated with the antiserum after being opened and drained. Recovery was rapid. No intravenous injections were given as there was no evidence of general dissemination of the infection.

572.

### Foreign Bodies in the Upper Air Passages.

D. WISSEKOVERY (*Arch. Internat. de Laryngol.*, November, 1926, p. 1052) gives his conclusions based on the study of twenty cases of impaction of foreign bodies in the air passages. The foreign body may cause complete obstruction, or act as a ball-valve, or produce a rigid stenosis of the bronchial tube. If inspiration is prevented, whether expiration is continued or not, it would be expected that a condition bordering on atelectasis would be produced, with consequent fixation of the diaphragm and lower ribs, and deviation of the mediastinum over to the affected side. The author states that this is, however, often not the case, and a condition of emphysema is produced, as would be expected where inspiration is still admitted and where expiration is prevented or hindered.

The ribs and diaphragm are again fixed and the mediastinum is displaced to the opposite side. In one case this condition culminated in a rupture, and a subcutaneous emphysema resulted. A violent attack of coughing appeared to be the deciding factor. Wiskovsky does not consider that the ball-valve condition is likely to persist for very long, since the inflammatory swelling of the bronchial mucosa will fix the obstructing body and probably completely close the tube. In experimental cases it is found that the air is absorbed by the blood, and the partial pressure of oxygen and carbon dioxide has become equivalent to that of the venous blood; but this does not hold good in pathological conditions in man.

573.

### Congenital Webbing of the Larynx.

R. GUASTALLA (*Arch. Ital. di Otol.*, September, 1926, p. 476) describes the case of a woman who had had a harsh unpleasant voice since infancy. At the age of 30 she began to have some dyspnoea, and on examination a triangular diaphragm was found between the anterior ends of the two vocal cords. The condition appeared to have existed from birth and there were no signs or history of tuberculosis, syphilis, or diphtheria. The author states that in a similar case the diaphragm was removed and was found to consist of a mass of interlacing fibres with a few blood vessels, a very small cellular content, but no glandular elements. He has made sections of the larynx of four early human embryos and found in all of them a fold at the anterior commissure. The fold was covered with mucous membrane and consisted of submucous connective tissue, with one or two glandular elements at its base. The upper portion of this fold appeared to take part in the formation of the epiglottis, but the lower part disappeared. This lower part was present in embryos of 6; and 7½ cm., but only a trace was found in embryos of 8 and 9½ cm. It is suggested that when this lower part, which lies at the level of the vocal cords, persists, it gives rise to the structure known as the congenital diaphragm or web of the larynx.

## Obstetrics and Gynaecology.

574.

### Painless Childbirth

D. DEUTSCHMAN (*Med. Journ. and Record*, October 6th, 1926, p. 421) records clinical observations on painless childbirth by the synergistic method of Gwathmey, which is based upon the interaction of magnesium sulphate, quinine, and ether shortens labour by softening the cervix and preserving the patient's strength for the stage of expulsion and the effects on the mother or child. The patient's eyes are covered and the ears closed with cotton-wool to diminish external stimuli; when the os has become dilated to diminish three fingers, with pains at about seven-minute intervals, an intramuscular injection of 2 c.cm. of a 50 per cent. solution of magnesium sulphate with 1/4 grain of morphine sulphate is given during one of the pains. If no sedative effect follows within twenty minutes another 2 c.cm. of the solution, without the morphine, is administered. With the advent of slight drowsiness a high retention enema is given of a warm mixture containing 20 grains of quinine, 45 minims of alcohol, and 2½ oz. of ether with olive oil up to 4 oz., the rectum and entire anal region being well lubricated with oil. This is usually followed by a semi-stuporous condition, but if no analgesia results within an hour a third administration of 2 c.cm. of solution should be given. The effect lasts about four hours, but if by then labour has not been completed the whole treatment, omitting the morphine, may be repeated. In a series of cases selected at random Deutschman found that the results were uniform and highly gratifying, and he claims that the method eliminates the painful sensations associated with the uterine contractions of the greatest part of the first stage of labour, frequently corrects malpositions, is simple and safe in performance, and without liability to post-partum haemorrhage or other complications.

575.

### Calcified Myoma.

G. JEANNERET (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, October, 1926, p. 484) remarks that calcification in a uterine myoma does not imply quiescence, and must be regarded, not as a favourable transformation, but rather as a complication which may cause a return of pain or bleeding or accidents due to compression. He records a case in which a woman, aged 48, who for ten years had been known to have a myoma of the body of the uterus (the tumour slowing stony hardness for one year), came to operation for rectal obstruction. The acute symptoms were due to pressure of two intrapelvic myomas, the size of the fist, which from microscopic examination and from the findings at repeated clinical examinations were believed to have developed

between the ages of 46 and 43. Acute abdominal symptoms had been caused by the older calcifying tumour on four occasions during the four years prior to operation. According to E. WEBER (*ibid.*, p. 523), calcification in uterine myomas begins as a rule in the centre and rarely affects the whole of a large tumour. Usually the myoma is pediculated and the most common complication is the separation—due to pedicular torsion or atrophy—of the calcified tumour, leading to formation in the case of a submucous myoma of a uterine calculus, or in that of a subserous one, of an abdominal foreign body which may perforate the bladder or rectum. Weber records a case of intestinal obstruction in an 11-year aged girl. The rectum had been compressed by a pediculated subserous homogeneously calcified myoma of the fundus weighing 25½ oz., but there were no peritoneal adhesions and the stalk was not twisted.

#### 576. The Prognosis of Cervical Cancer.

A. PLAUT (*Surg., Gynecol. and Obstet.*, October, 1926, p. 450) has considered the possibility of basing the prognosis in cervical carcinoma on the type of the tumour cell present, whether spinal, transitional, or fat spindle cells, and concludes that the histological picture of this condition does not allow groups to be defined according to the type of cancer cell found. In determining prognosis constitutional factors have also to be considered and the influence of age must be remembered. Plaut therefore believes that the clinical classification of this disease remains the best prognostic aid, though the general histological aspect of the tumour may assist. His conclusions were based on the clinical and histological data of 149 cases, and he found that tumours with a very irregular form of growth were usually associated with early death. Adenocarcinoma of the cervix was excluded from the investigation.

#### 577. Repair of the Lacerated Cervix.

A. MUELLER (*Zentralbl. f. Gynäk.*, October 16th, 1926, p. 2697) describes his method of dealing with a torn cervix in a private home with or without assistance. Severe lacerations may occur spontaneously, are not uncommon, and may be suspected when unusually severe pain is observed. Mueller uses either two Winter's toothed forceps, which hold the soft cervix better than an ordinary volsellum, or Mauermeier's, in which the teeth are placed sideways. The forceps are applied to the anterior and posterior lips, and the cervix is pulled down. While one hand holds the forceps, the other investigates the direction and extent of the tear; the bleeding may be temporarily controlled by applying forceps to the apex and ends of the tear. The author uses a suture which can be easily sterilized and left in indefinitely, and large size fully curved needles to give as wide a grip as possible. If no assistance is available the suturing must commence below; the left hand pulls down the cervix and its forefinger controls the stitch from within, making sure that it goes through the whole depth of the wall. A Kocher's forceps is put on the end of each suture; the cervix is thereby pulled further down and the tear stitched upwards to its apex. The last suture is particularly important, as it must catch the torn vessels; the ureter is not likely to be included, but the possibility should be kept in mind. If an assistant is available he should hold the retractor and pull down the cervix; the suture may begin from above downwards and is controlled by the finger as before. When no instruments are at hand haemorrhage may be arrested by Dührssen's method of packing; if nothing else is available, freshly washed linen cloths, boiled or wrung out of an antiseptic solution, may be used. Before packing is performed the vulva and surroundings, and the operator's hand and forearm, should be thickly smeared with germicidal soap, which lubricates the parts and is more suitable for such manipulations than chemical antiseptics like iodine, which dry up the passages.

### Pathology.

#### 578. Effect of Heat on Serum Agglutinins.

C. A. MALLARDO (*Il Morgagni*, September 19th, 1926, p. 1185) has studied the effect of heat on serum agglutinins. An anti-*coli* serum of a titre of 1 in 500 was divided into four portions, which were heated at 55°, 60°, 65°, and 70° C. respectively for thirty minutes. Each portion was then put up against a suspension of *B. coli* and incubated for six hours. The titre of the serum heated to 55° was now only 1 in 400; of that heated to 60° only 1 in 200; of that heated to 65° only 1 in 100; and of that heated to 70° less than 1 in 50. The same serum was now diluted 1 in 5, so as to have a titre of 1 in 100; this diluted serum was divided into four portions as before, and each was heated for thirty minutes. The result of the agglutination test now showed that the portion heated to

55° had a titre of only 1 in 40; that heated to 60° of 1 in 20; that heated to 65° of 1 in 10; while that portion heated to 70° had no agglutinating power whatever. From these experiments it would appear that the effect of heat on the agglutinating power of a serum depends primarily on its content of agglutinins; in the case of a high titre serum exposure to heat of given intensity for a specified time will apparently be much less than in the case of a low titre serum; in the former instance the agglutinin titre will be lowered, in the latter instance it may be completely abolished. The practical conclusion is that if it is wished to compare the effect of heat on two or more different sera they should first of all be diluted till they are of the same titre. Experiments were performed to test this conclusion. Serums prepared against *V. cholerae*, *B. proteus*, and *B. pest* were diluted till the titre for their homologous antigens was the same. Each was divided into four portions, which were exposed to heat in the specified manner. When put up against their respective antigens they all gave the same readings. Thus, all those portions heated to 55° agglutinated to 1 in 40; all those heated to 60° agglutinated to 1 in 20, and so on. The author would explain the discordant results so frequently reported in the past by assuming that the serums compared were not of the same titre, and were therefore affected to different degrees by the same amount of heat.

#### 579. Topographical Selectivity of Bacteria.

A. C. NICKEL (*Journ. Amer. Med. Assoc.*, October 2nd, 1926, p. 117) reports a number of experiments on rabbits injected with streptococci recovered from patients suffering from arthritis, myocarditis, and lesions of the stomach, eye, and skin. The general results indicated that the organism tended to settle in those parts of the body which were attacked by disease in the patient. Thus a strain of streptococcus cultured from the teeth, tonsils, or other situation of a man suffering from arthritis was more likely to give rise to arthritis in rabbits than was a strain recovered from a patient with myocarditis or gastric ulcer. Of 328 rabbits injected with cultures from patients with arthritis 51 per cent. developed arthritis and only 5 per cent. lesions of the stomach; whereas of 190 rabbits injected with cultures from patients with gastric or duodenal ulcer 40 per cent. had lesions of the stomach and duodenum, and only 6 per cent. developed arthritis. Again, 39 per cent. of animals injected with streptococci from patients with myocarditis developed heart lesions, whereas only 3 per cent. of animals injected with strains from arthritic or gastric patients developed heart lesions. The highest incidence of specific localization was observed in cultures taken from infected teeth.

#### 580. Bactericidal Power of the Blood and Serum.

A. GEORGEVITCH (*C.R. Soc. de Biologie*, October 22nd, 1926, p. 954) has studied the bactericidal power of human serum for a number of intestinal organisms. The blood was drawn aseptically, and the serum used within the first twenty-four hours. A drop of an eighteen-hour broth culture, diluted in saline, was added to 0.5 c.c.m. of serum in a small tube; a similar drop was added to 0.5 c.c.m. of saline in another tube, which acted as a control. The number of organisms alive at the start and after varying times of incubation at 37° C. was then determined by plating on agar. The results showed that all the bacilli studied—four strains of dysentery, *B. typhosus*, *B. paratyphosus* A and B, and *V. cholerae*—were killed in six hours by a normal serum. Not all serums, however, were equally active. The actual time taken for destruction of the organisms apparently depended to some extent on the initial inoculation, but even when a considerable number of organisms were added, the mixtures were sterilized in a few hours. *B. coli* proved resistant; a few organisms perished during the first hour or two of contact, but afterwards multiplication began and increased, till in twenty-four hours the number of colonies was too great to be counted.

581. L. K. WOLFF (*Nederl. Tijdschr. v. Geneesk.*, September 25th, 1926, p. 1411), as the result of experiments on rabbits, concludes that by the intravenous injection of dead staphylococci, or by rubbing living staphylococci into the skin, it is possible to confer a bactericidal power on the blood which it did not possess previously. This acquired bactericidal power is specific, being caused by leucocytes which kill the bacteria rather than by phagocytosis. The serum or plasma itself does not appear to contribute to the formation of this bactericidal power. The blood and serum of normal and immunized rabbits agglutinate staphylococci. Wolff has not found that the addition of antistaphylococcal serum has any favourable effect on the bactericidal action on staphylococci either *in vivo* or *in vitro*. The bactericidal power of the blood is diminished or destroyed by the addition of staphylococcus toxins.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 582. Syphilitic Pleurisy in Congenital Infection.

AFTER reviewing the literature on congenital syphilitic affections of various organs, especially the lungs, G. MACCIOTTA (*La Pediatria*, October 15th, 1926, p. 1097) describes two cases of well marked congenital syphilis with pleurisy of lentic origin. The first patient at the age of 3½ developed movements, which were relieved by lumbar puncture and rapidly cured by anti-syphilitic treatment. The second case was that of an infant aged two months, with severe signs of congenital syphilis and dyspepsia, which, after several courses of treatment, yielded rapidly to mercury and arsenobenzol. In both cases coexistent tuberculous and rheumatism were excluded. The pleuritis which developed, bilateral in the first case, were dry at first and characterized by an unusually rasping rub. Subsequently a moderate effusion formed, the fluid not being characteristic in any way. The pleurisy apparently started in the shape of a triangle, with one side in the paravertebral line, and extending obliquely outwards. In both cases was in the shape of a triangle, with one side in the paravertebral line, and extending obliquely outwards. It was surrounded by an increasingly resonant area of irregular shape, and there was no evidence of involvement of the lung. The signs rapidly cleared up under treatment with mercury and arsenobenzol, after salicylates and foides had failed. The onset of the pleuritis had been accompanied by great restlessness and pain. The cough was suggestive of pertussis. Macciotta considers four possibilities in the production of a syphilitic pleurisy: extension from the lungs, from a mediastinitis, from syphilitic tracheo-bronchial glands, and a primary involvement of the pleura. He places these two cases in the last class.

### 583. Prophylaxis of Measles.

W. H. PARK and R. G. FREEMAN (*Journ. Amer. Med. Assoc.*, August 21st, 1926, p. 556) report upon the prophylactic use of measles convalescent serum from observations upon over 1,500 children who received preventive injections; in 979 cases the data as to exposure, dosage, and ultimate success were fairly accurate. The exposure was direct in 630 and indirect in 349. No bad results followed the injections. It was found that 6 c.cm. of convalescent serum or plasma injected into a child under 3 years of age, and from 6 to 10 c.cm. for older children, usually sufficed to prevent infection, giving immunity for about a month; if infection followed, the attack was modified and uncomplicated, and the immunity lasting. The serum contained the greatest accumulation of antibodies shortly after the patient's convalescence, and at the end of three months these were still abundant though probably in small amount. They conclude that by its prompt use serious pneumonia complications. The method of preparation is described, but the difficulty of obtaining a continuous supply of blood for the purpose. S. V. HAAS and J. BLUM (*Ibid.*, p. 558) conducted a similar investigation upon 174 children. The plasma was collected from one to four months after defervescence, and was stored for from one-half to four and a half months before being used. It was found that 5 per cent. of all the children were protected for three weeks and 51 per cent. for three months or more, while with plasma injected one and three months after defervescence 89 per cent. were protected for three weeks; the earlier the plasma was collected after defervescence the greater was its protective value. Of the 174 children injected with plasma collected form of measles without any complications. There appeared to be very little difference in the protective value of plasma injected from the fourth to the seventh day after exposure, but if injected still later it did not protect or modify the disease. The authors found that injections of more than 41 per cent. of cases, and where it failed to protect it modified measles developing even two months after injection. They regard the prophylactic use of convalescent blood as valuable for institutions and in private cases in which the duration of the exposure is known.

584. J. A. TOOMRY (*Amer. Journ. Dis. Child.*, September, 26, p. 401) records his observations on the prophylactic use of measles convalescent serum at the Cleveland City Hospital,

Babies' and Children's Hospital, and in private practice. The serum was obtained from donors eight days after the rash began to disappear, was inactivated one hour at 56° C., and sealed and stored in ice, no preservative being added. In some cases the serum was eight to twelve months-old and still seemed to be potent. Intramuscular injections of 3 to 10 c.cm. of convalescent serum were given to 389 persons in all who had been exposed to measles; only 21 contracted measles—13 before and 8 after the original incubation period of fourteen days. In all the injected cases, however, the symptoms and signs of measles were attenuated.

585. S. PROGULSKI and F. REDLICH (*Klin. Woch.*, August 6th, 1926, p. 1461) report on the prophylactic measles serum prepared under Degkwitz's directions from sheep. The injection consists of 1 to 2 units (10 to 20 c.cm.) of the serum between the seventh and tenth day of the incubation period. With the exception of Wiese, subsequent investigators with this serum, such as Kaupé, Kochmann, and Mosse, could not confirm the good results obtained by Degkwitz. From trial of the animal serum Progulski and Redlich conclude that Degkwitz's serum has no power to protect children from an attack of measles; that it exercises no attenuating effect upon the course of the disease, and does not prevent serious complications; and that in most cases it causes an unpleasant serum sickness, and often has an inhibitory action on the appearance of the symptoms of measles, so that the incubation period is prolonged.

### 586. Hyperleucocytosis in Whooping-cough.

A. G. MITCHELL and L. S. FRIEDMAN (*Arch. of Pediat.*, September, 1926, p. 617) review the literature and record a case of a male infant, aged 4 months, in the third week of whooping-cough complicated by bronchopneumonia, who had a white blood cell count of 233,608, of which 48 per cent. were polymorphonuclears, 45 per cent. lymphocytes, 3 per cent. large mononuclears, 2 per cent. transitional, and 2 per cent. unclassified cells, a few of them resembling myelocytes. The platelets seemed normal in number. No necropsy could be obtained, so that leukaemia was not absolutely excluded, but the absence of splenic or marked lymphatic enlargement, the apparently normal number of platelets, the age of the patient, and the history did not suggest that diagnosis.

## Surgery.

### 587. Cholecystitis in Situs Transversus.

R. B. BUTTMAN and H. P. BINSWANGER (*Amer. Journ. Med. Sci.*, October, 1926, p. 570) report a case of acute cholecystitis associated with transposition of the viscera. The patient, aged 49, was admitted to hospital with a history of being awakened that morning with an excruciating pain in the abdomen, radiating along the costal margin into the left scapular region. He was nauseated and vomited once. There had been two previous attacks separated by an interval of several years. He had never been jaundiced nor had he noticed clay-coloured stools. On examination the right side of the abdomen was slightly icteric; the temperature was 100.6°; the white cell count was 20,500. He had severe pain in the upper part of the left side of the abdomen and there was definite tenderness and rigidity over this area. The right side of the abdomen was not tender and showed no rigidity. From the examination of the abdomen it would have been impossible to make a definite diagnosis. The most probable explanation would have been an infarct of the spleen, a left paraneuritic abscess, or perhaps a perforating ulcer of the cardiac end of the stomach. Examination of the chest showed that the heart was on the right side, with the apex beat definitely palpable in the right mammary line. There was no dullness under the right costal margin; where the usual liver dullness should have been there was very marked tympany. X-ray examination after a barium meal showed the stomach to be on the right side, the duodenum crossing over towards the left. A typical gall-bladder shadow as well as a "gall-bladder seat," or filling defect of the duodenum, was seen by radiological examination to the left of the mid-line. The day following admission to hospital the patient felt very much better, and except for a slight increase in the subicteric tint of the sclerotics was apparently well. Palpation of the

100 DEC. 25, 1926]

## EPITOME OF CURRENT MEDICAL LITERATURE.

[THE BRITISH  
MEDICAL JOURNAL]

abdomen now definitely revealed the liver border under the left costal margin. Two days later the symptoms had completely disappeared except for a slight tenderness over the region of the left-sided gall bladder. The patient refused further treatment and went home the following day feeling quite well. An electro-cardiogram showed an inversion of all the deflections in Lead I, indicative of dextrocardia. The patient was right-handed; the right testis was lower than the left. The rectal examination gave no assistance in the diagnosis of transposed viscera. The patient was not a twin. The authors add that this case indicates the necessity for making a complete physical examination in all obscure abdominal conditions.

## 588. Treatment of Diffuse Peritonitis.

The bactericidal action of acid solutions has been attributed to the hydrogen-ion concentration, and L. SCHÖNBauer (*Zentralbl. f. Chir.*, November 6th, 1926, p. 2834) finds that the best bactericidal results were obtained by a mixture of 4.5 c.cm. of dilute hydrochloric acid, 1,500 c.cm. of sterilized distilled water, and 1 gram of pepsin (digestive power 1 in 3,000). This solution has been used in the treatment of diffuse peritonitis following the perforation of gastric and duodenal ulcers. The author finds that pepsin increases the activity of the 3 per cent. hydrochloric acid solution, and that when 1 to 1.5 litres of this solution are introduced into the peritoneal cavity of healthy dogs the presence of the acid cannot be recognized after five minutes at the most. Schönbauer describes the case of a man, aged 47, with severe general peritonitis after a perforated duodenal ulcer. The abdominal cavity was irrigated with three litres of the acid pepsin solution, and the wound was closed in three layers; the patient made a complete recovery. Schönbauer states that between January, 1922, and July, 1926, 117 patients were treated by this method at Eiselsberg's clinic with a 12.8 per cent. mortality. In this clinic the death rate, following perforation of the stomach, prior to the introduction of this treatment, was 28 per cent., while among 71 cases treated with the solution the death rate fell to 9 per cent. Ten patients with perforation of the appendix, submitted to early operation and treated with the solution, recovered without a single death. Similarly, in perforation of the gall bladder, of 6 patients treated without the acid pepsin solution 3 died—a death rate of 50 per cent., while among 6 other patients suffering from the same disease there were no deaths. To summarize the results: among 164 cases in which the solution was not used there was a death rate of 34.8 per cent., as compared with 117 patients treated with the solution of whom only 15 died—a death rate of 12.8 per cent. The value of such biological antiseptics is clearly shown by the facts that there was no other variation in technique, nor were the operations performed earlier.

## 589. Diffuse Gastric Polypsis.

H. BRUNN and F. PEARL (*Surg., Gynecol. and Obstet.*, November, 1926, p. 559) report five proven and seven probable cases of diffuse gastric polypsis (adenopapillomatosis gastrica) with a study of every case (84 in all) reported in the literature. They ignore single isolated growths and deal only with cases showing three or more benign epithelial polypoid growths of the gastric mucous membrane; 55 per cent. of the cases occurred between 50 and 70 years of age, the proportion of males to females being three to two. The condition may be either congenital in origin or arise from an inflammatory basis, and it may occur as distinct adenomatous polyps or as slightly elevated hypertrophic plaques, en masse variety, probably telangiectatic in origin. Symptoms may be entirely absent, but when present are those of any gastric disorder—namely, epigastric pain, distension, vomiting, etc. Achylia is almost always present, and this, combined with the presence of fresh blood and abundant mucus, should suggest the diagnosis. Haematemesis is rare, but occult blood is frequently present. Pedunculated masses, especially in the region of the pylorus, are more likely to produce symptoms than broad-based ones and those on the greater curvature. Radiograms properly interpreted are said to offer the most valuable aid in diagnosis, the characteristic finding being irregular defects in the margin of the shadow at the site of the tumours, which are usually upon the greater curvature; gastroscopy and examination of shreds in gastric washings are also useful diagnostic factors. Treatment is surgical, and since malignant degeneration is liable to occur, as much of the tumour area as possible should be excised and the remaining polyps be individually excised and their bases thoroughly cauterized. Local anaesthesia, with or without splanchnic block, was found the most satisfactory type.

## Therapeutics.

## 590. Treatment of Typhus by Injection of Cerebro-spinal Fluid.

C. ZIELINSKI (*Paris méd.*, September 18th, 1926, p. 225) records his observations on the treatment of certain infections by subcutaneous or intravenous injection of the patient's cerebro-spinal fluid. The accumulation in it of antibodies due to some elective action of the choroid plexus (Stern) or to permeability of the vessels in morbid states (Kafka) indicate that the cerebro-spinal fluid has curative properties. When employed at the suitable moment in typhus (the treatment was found to shorten the duration of the disease; it has more soothing effect than any narcotic, raises the blood pressure, increases diuresis, and facilitates deglutition). Sometimes the results were very striking, and patients who the day before the injection had been in a grave condition became convalescent the following day. Zielinski concludes that injection of the patient's cerebro-spinal fluid should be employed in all severe cases of typhus on the eighth or ninth day of disease. The treatment should also be tried in cases of meningitis and lethargic encephalitis, but only in the initial stage of the disease, since the fluid is infected late throughout the spinal canal, and its use can only rarely give rise to good results.

## 591. Treatment of Staphylococcal Infections by the Bacteriophage.

P. HAUDUROX, P. CAMUS, and R. DALSACE (*Presse Méd.*, September 22nd, 1926, p. 1195) review the work of Hével and other investigators on the action of bacteriophages in infectious diseases. They themselves concentrated on staphylococcal infections; the cases treated including cutaneous, oto-rhinological, and uro-vesical conditions. The bacteriophages used were particularly active, and were prepared according to the method of Haudurox. The authors state that the greatest precautions should be taken to secure sterility of the bacteriophage; it should never contain even a trace of visible organized element, and rigorous control tests should be made. Before commencing treatment the authors always test *in vitro* the lytic power of the bacteriophage. They assert that the activity and polyvalence of the bacteriophage used was such that the very great majority of staphylococci were lysed *in vitro*, and that treatment is useless unless such control lysis occurs. Treatment should be both general and local. The general treatment consists of two or three injections (subcutaneous) at twenty-four-hour intervals of 2 c.cm. of the bacteriophage. It is said to be useless to increase the dose, and under no pretext should more than

in peptone water or bouillon, the injection of which into the veins causes a grave and, possibly fatal, general reaction. Local treatment aims at carrying the curative product into contact with the infective focus. In such conditions as furunculosis and anthrax the injection is made around or into the lesion itself. If the focus is open and suppurating, compresses of lint soaked in the bacteriophage can be applied. In other cases, applications with a brush (as in mycosis), local baths, and gargles can be given. If vesical or renal infection is present, 10 to 15 c.cm. of the bacteriophage should be introduced into the bladder or pelvis of the kidney to be retained by the patient as long as possible. Local treatment can be repeated four or five times. During the course of treatment, all medication by antiseptics or quinine salts should be stopped as these have an antibacteriophage action. The authors state that the administration of this bacterial principle produces only slight reactions and that the results are excellent and rapid, the symptoms subsiding in a few days.

## 592. Ultra-violet Rays in Tetany.

In view of Woringer's discovery that ultra-violet rays caused rapid diminution of mechanical and galvanic excitability, and of other tetanic manifestations, with a corresponding increase of the blood calcium to normal, M. MIRAGLIA (*La Pediatria*, October 15th, 1926, p. 1116) similarly treated twelve children suffering from tetany. Nine of the patients had extrinsic signs of tetany; in three of these there was also laryngospasm, in two carpopedal spasm; and in seven rickets. In the three remaining cases the tetany was latent. In all the blood calcium showed a low level varying from 58 to 80 mg. per cent. (Waard's method). Three healthy and two epileptic children were taken as controls. In these the lowest blood calcium level was 110 mg. per cent. In four other cases of simple rickets, in which no single evidence of tetany could be elicited, the lowest blood calcium was only 98 mg. per cent. No drug which could influence the spasmodic

or the blood calcium was administered during the investigation. A single exposure, lasting from a minimum of five minutes to a maximum of thirty-five minutes, was made on alternate days, increasing by five minutes; the total exposure being six hours forty-five minutes. A Hanau's lamp at one metre distance was used. Miraglia concludes that hypocalcaemia is a constant finding in tetany, and that its absence in cases of other convulsive disorders is of value in the differential diagnosis. There is no correspondence between the hypocalcaemia level and the degree of manifestation of the tetany. Ultra-violet rays are capable of raising the blood calcium level to normal over a long period. With the return to normal the clinical signs of spasmodophilia disappear first and then the mechanical and electrical phenomena.

593. **Treatment of Eczema with Intravenous Saline.**  
J. SELLIER, T. BANSOY, and E. LIENNER (*Med. Klin.*, October 15th, 1926, p. 1610), having noted the good effect of intravenous injections of 10 per cent. sodium bromide on moist eczematous conditions, conducted experiments to determine whether this was due to the sodium or to the bromine ion. They came to the conclusion that the former was concerned, and they therefore gave sodium chloride in 10 c.cm. doses daily for six to nine days with equally good if not better results. In the treatment of twenty-eight cases, including both chronic and acute types, only five patients did not improve, and in no cases did any ill effects follow the treatment. The authors remark that it was an old custom to treat skin conditions by the subcutaneous or intravenous injection of large quantities of normal saline solution, and that their method is merely a simplification of this procedure. They offer no explanation as to the rationale of the treatment.

## Radiology.

594. **Radiography in Fracture of the Pelvis.**  
VERGOZ (*Rev. de Chir.*, No. 5, 1926, p. 273) observes that radiography has shown that pelvic fractures are far more common than has been believed hitherto. The clinical diagnosis is sometimes very difficult; when the fracture is not accompanied by gross displacements or visceral injuries it may not be recognized, but be diagnosed as contusion of the hip. Single skiagrams often fail to reveal certain forms of fracture, especially when situated in the posterior arch of the pelvic girdle. Vergoz therefore maintains that stereoscopic radiographs should always be obtained in cases of injuries to the pelvis of uncertain nature. The patient's pelvis is immobilized on a couch fitted with drawers, in which the films are introduced. The distance between the antecathode and the film is 60 cm. After having been placed on the region to be skigraphed the tube is displaced 2.5 cm. towards the right, and in that position the first skiagram is taken; the tube is then carried 2.5 cm. to the left of the centre and a second skiagram is taken. The author cites numerous examples of various kinds of pelvic fractures in support of his contention that stereoscopic photographs are essential for accurate diagnosis of the site and nature of these injuries.

## Radiation Therapy in Carcinoma.

595. **Radiation Therapy in Carcinoma.**  
G. W. HOLMES (*Boston Med. and Surg. Journ.*, August 26th, 1926, p. 393) remarks that during the past five years important data have been obtained with regard to the therapeutic use of radium and of x rays. The complete destruction of diseased tissue by radiation is unlikely unless the lesion is superficial or so accessible that radium can be brought directly in contact with it. The most favourable results are obtained in cancer of the uterine cervix and in cancer of the mouth or skin. Short wave rays appear to have a greater selective action, and should be used when complete destruction of malignant cells is attempted. For this reason curable cases are treated by heavily filtered rays, but this is sometimes impracticable, as when the lesion is deeply seated or resistant. In these cases interstitial radiation may be necessary. This may be employed by implanting glass seeds containing radium emanation in the mass, or by inserting needles containing radium salt or emanation; the latter is preferable as the needles shut off the caustic beta rays, and more complete destruction of malignant tissue results with less discomfort to the patient. Incurable cases may be divided into two groups—primary lesions and post-operative recurrences; in both, the treatment is necessarily only palliative. Holmes believes that it is seldom advisable to use prolonged or very heavy dosage, since this may result in radiation sickness, producing rapid exhaustion and swift reduction of the number of the circulating lymphocytes, which are of great importance in combating the advance of a malignant growth. There is

considerable evidence of the value of small stimulating doses in the treatment of these cases, and Holmes considers that there is no scientific basis for the theory that small repeated doses stimulate malignant tumours. It is more probable that if heavy radiation fails to destroy all malignant tissue the surrounding healthy tissue is so damaged that it offers little resistance to the growth of the remaining cancer cells. Radiation probably does more harm than good to patients who are definitely cachectic. The author thinks that pre-operative radiation should be more generally used, especially in borderline cases or in those of a very malignant type. Though post-operative irradiation is rather general there is little evidence that it prevents recurrence or prolongs life. Irradiation in some form may relieve excessive pain. Holmes concludes that most curable cases are better treated surgically; a radical cure should not be attempted when complete removal is impossible; such cases are better treated by radiation only. Pre-operative radiation properly used probably increases the chance of surgical cure. Post-operative radiation has failed to prevent recurrence, and when prolonged has caused permanent damage to the skin. In the treatment of recurrent and of inoperable cases the main object should be the relief of distressing symptoms.

## 596. Erythrocythaemia Successfully Treated by X Rays.

G. MILANI (*Il Policlinico, Sez. Med.*, October 1st, 1926, p. 547) reports a case of erythrocythaemia in a woman aged 30. The disease started about five years ago with unusual redness of the face and lips, outbreaks of urticaria, severe headache, palpitation, cyanosis, and enlarged spleen. The red corpuscles numbered 12,000,000 per c.mm. and the white 12,000. The von Pirquet test was negative. By watching the effect of x rays on the spleen or bone marrow the author concluded that the disease was not due to diminished erythrolysis or to a primary splenic lesion. When the x rays were directed to the long bones only, the red corpuscles diminished and at the same time the spleen decreased in size. Milani thinks that, although the spleen is not primarily at fault in this condition, it probably plays a secondary part by inducing the production of erythrocytes in the bone marrow. Some of this patient's blood was injected into a child suffering from pernicious anaemia, without producing any improvement. Irradiation of the tibiae and knees caused a diminution of the erythrocytes and also an improvement in the symptoms, which has lasted for a year. After treatment the erythrocyte count dropped to 6,400,000, leucocytes to 5,000, haemoglobin 120 per cent., and the patient was able to work comfortably. The main feature in the treatment was irradiation of the bones and not the spleen.

## 597. Ultra-violet Rays in the Treatment of Pyorrhoea.

F. TALBOT (*Brit. Journ. of Dental Science*, October, 1926, p. 295) describes the treatment of pyorrhoea by means of erythema doses of ultra-violet rays administered to the skin of the trunk with the object of mobilizing the defence powers of the body against bacterial infection. He states that the small number of cases treated with apparent success by vaccines show a very high ratio of relapse. After eighteen months' experience of the value of treatment by ultra-violet rays the author claims that it deserves to be regarded as a specific cure in cases of pyorrhoea with systemic infection. Early cases of this type clear up after two or three doses, and the health of the sockets can, in his opinion, be maintained by monthly erythema doses from natural or artificial sources, of ultra-violet rays. In some cases the low resistance of the patient appeared to have been due to temporary causes, and health has been maintained without a repetition of the treatment; but this cannot be looked for in those who are subject throughout the winter to an inadequate exposure to sunlight. The work of H. K. Box of Toronto is adduced as evidence that regeneration of alveolar bone may occur under the advantageous conditions induced by ultra-violet medication.

## Obstetrics and Gynaecology.

### Caesarean Section in Two Stages.

598. LAFONT, HOUILL, DUBOUCHER, and JAHIER (*Ann. Soc. d'Obstet. et de Gynecol. de Paris*, October, 1926, p. 473) report two cases of the operation of Portes, in which the uterus, drawn out of the abdomen as a preliminary to Caesarean section in infected patients, is left in the same situation at the end of the operation and returned to the pelvis at a later intervention (see *Epitome*, 1924, vol. ii, para. 454, and 1925, vol. i, paras. 250 and 327). To the few recorded fatalities the present authors add another in a primipara, aged 22, with a breech presentation and prolapse of the cord. Extraction was impeded by a partly ectopic and partly solid tumour of the child's axilla, and was found impossible even after

division of the tumour by scissors. After abdominal corporeal hysterotomy the uterus was left outside the wound, but the uterine suture did not hold, and a slough formed which was irrigated with Dakin's solution. The exteriorized uterus became gangrenous; Porro's hysterectomy was performed without anaesthesia on the eighth day, but the patient succumbed. In another case a young two-para with a generally contracted pelvis, who had undergone conservative Caesarean section a year previously, was admitted to hospital at term with a temperature of 102°, a tonically contracted uterus with an incompletely dilated cervix, and a living foetus presenting by the vertex. After the operation of Portes the uterus sloughed in the neighbourhood of the incision, but good union was eventually obtained after prolonged suppuration. The uterus was returned to the pelvis fifty-seven days after its exteriorization, and, on the patient's discharge eighteen days later, the organ, although not freely movable, was of approximately normal size and antverted. The child survived.

#### 589. Epilepsy and Pregnancy.

C. CLEMMESSEN (*Ugeskrift for Læger*, October 31st, 1926, p. 939) has studied the effects on each other of epilepsy and pregnancy in two series of cases. The first consisted of 43 epileptic patients treated in the Aarhus maternity hospital between 1910 and 1926, during which period there were about 13,000 confinements. These 43 patients gave birth either in the maternity hospital or elsewhere to a total of 97 children. The second series consisted of 22 patients who had undergone a total of 61 pregnancies, and were admitted to a hospital for epilepsy in 1925 and 1926. In the first series of 43, there were 6 women who had aborted nine times, but in the second series there was no instance of the disease having a direct effect on the pregnancy. With regard to the influence of the pregnancy on the epilepsy, it was noteworthy in this series that in as many as 7 cases the epilepsy recurred during pregnancy after the patients had been without symptoms for several years. In 107 pregnancies taken from both series, accurate data were obtained with regard to the influence of the pregnancy on the disease, and in 54 it was found that the attacks of epilepsy had started or become more frequent in connexion with the pregnancy. In 28 cases the pregnancy had not affected the disease, in 18 the disease had shown signs of improvement during the pregnancy, and, finally, in 7 cases the disease had become worse at the beginning of pregnancy and had shown improvement towards its end. As for the fate of the children born to these epileptic mothers, accurate information was lacking in several cases for want of "follow-up" investigations, but details were obtained about 60 infants born alive to 29 epileptic mothers. Twelve of these infants had died young, 6 dying in convulsions. The author concludes that pregnancy often stirs up afresh an epilepsy which has been latent, or renders already existing epilepsy more serious; he recommends hospital treatment for every epileptic pregnant woman throughout her pregnancy.

#### 600. Visceroptosis in Women.

G. CARAJANNOPOULOS (*Rev. de Chir.*, 1926, No. 7, p. 535) considers that the obscure condition of visceroptosis depends on a loss of tone and atrophy of the muscles of the abdominal wall and pelvic floor. This, he thinks, is the result of deficiency of the internal secretion of the ovary acting through the sympathetic system. In the great majority of women affected with visceroptosis there is a history of menstrual trouble due to a loss of ovarian secretion. Many of these patients have had a previous attack of some acute infection, such as typhoid fever, or give a history of old pelvic infection due to metritis. This has resulted in atrophy or degeneration of the ovary, associated with visceroptosis; there may be certain functional troubles, such as palpitation, flushings, and other examples of vasomotor instability, which often accompany disorders of menstruation. It is suggested that the loss of ovarian secretion acts on the muscular system through the sympathetic nerves, and as the result of loss of muscle tonus general visceroptosis is produced.

#### 601. Oöphoralgia Erotica.

M. POROSZ (*Urol. and Cutan. Rev.*, October, 1926, p. 592) in 1900 described under the name of "epididymitis sympathica" a clinical phenomenon resembling epididymitis, but in which there was no infection and the urethra and prostate were not inflamed. The epididymis was swollen, but the pain connected with it ceased after ejaculation, and the condition subsided. The symptom usually came on after sexual excitement which was not satisfied, or not followed by ejaculation, but it might also be caused by nervous apprehension or by the passage of a hard motion from the bowels. Porosz has recently observed a corresponding condition in the female sex. The subjects were mostly young women who had been married for one to seven years; they complained of pain on

both sides of the lower part of the abdomen. On examination the ovaries were found to be entirely free from adhesions but tender to the touch; the vagina, urethra, and cervix were quite free from tenderness. No signs of acute or chronic gonorrhoeal or catarrhal lesions were detected. Treatment by warm sitz baths, salt baths, Priesnitz packs, and other balneological measures was ineffective. The condition was found to be due to the failure of the husband, through sexual neurasthenia caused by atony of the prostate, to produce orgasm in the wife. Treatment, therefore, in such cases should be directed towards improving the husband's condition.

## Pathology.

#### 602. A Simple Method of Demonstrating Tubercle Bacilli

G. MAXER (*Centralbl. f. Bakt.*, October 8th, 1926, p. 10) has worked out a simple method for demonstrating tubercle bacilli when these are present in only small numbers in pathological fluids. The sputum, for example, is collected in a glass vessel, which is then nearly filled with Kuczynski Standard 1 bouillon; a woollen plug is inserted and the fluid is incubated at 37° C. for three days, being shaken frequently. The upper clear layer is then decanted, and the remainder centrifuged for one hour. Films are made from the sediment and stained in the usual way. This method provides the bacilli with a suitable culture medium in which they are able to multiply, so that in a few days' time they can be demonstrated without difficulty. The method, with slight modifications, is said to be suitable for demonstrating the bacilli in urine, faeces, pus, pleural fluid, and other pathological material.

#### 603. Food Value of Vegetable Juices.

EVA M. DAVIS and HANNAH A. STILLMAN (*Amer. Journ. Di. Child.*, October, 1926, p. 524) report the results of a series of experiments planned to show the comparative growth-promoting qualities of some of the fruit and vegetable juices recommended as cheap substitutes for orange juice in infant and child feeding. The juices most commonly recommended are tomato, cabbage, spinach, and carrot. All these compare favourably with orange in their mineral content, and, with the possible exception of carrot, they appear to be similar able to prevent scurvy. Young albino rats were used for the experiment. It was found that the minimum amount of orange or tomato juice which would support normal growth in the rat was 9 c.cm. The same quantity of spinach or carrot juice gave equally good results. While winter cabbage was not satisfactory, fresh summer cabbage was found to be comparable in growth-promoting power with the other juice used.

#### 604. The Haematology of Congenital Syphilis.

G. ZANCA (*Arch. de Méd. des enfants*, September, 1926, p. 505) who reports forty-five illustrative cases, states that apart from anaemia it is usual to find one or more of the following blood changes in congenital syphilis: the haemoglobin value is rarely normal, but is either above or below the normal; if almost a rule for the number of red cells to be below normal leucocytosis is frequent; the leucocyte formula, which is always abnormal, is characterized by a mononucleosis of the lymphocytic type and the frequent presence of abnormal elements, which are usually the mother cells of the granulocytic series. Like Tixier and Weissenbach, Zanca divides syphilitic anaemia in the infant into two separate groups—namely simple anaemia, in which the number of red cells keeps above two million, and severe anaemia, in which the number of red cells is usually below two million. The course is rapid and the constitutional disturbance severe. Severe anaemia may be subdivided into two principal types—namely, severe anaemia of the pernicious type, and splenic or pseudo-leukaemic anaemia. Of the pernicious type of anaemia the following four varieties of the plastic form may be distinguished: (1) pernicious anaemia of the orthoplastic form or with a normoblastic reaction, shown by the normal myeloid reaction; (2) pernicious anaemia of metaplastic form, shown by an embryonic myeloid reaction; (3) pernicious anaemia of hypoplastic form characterized by an attenuated reaction in the circulating blood in contrast with the well marked reaction in the bone marrow; (4) aplastic anaemia, very rare in infancy, which is characterized by the absence of any myeloid reaction. Four varieties of pseudo-leukaemic anaemia are described: (1) A myeloid form, which is much the commonest, characterized by increase of the polymorphonuclears and the presence of myelocytes, mostly of the neutrophil type, in the proportion of 2 to 10 per cent.; (2) a lymphoid form, in which the lymphocytes predominate; (3) a mixed form characterized by an equally marked proliferation of granulocytes and lymphocytes; (4) an eosinophilic form with a high percentage of eosinophils.
